A Penalized Synthetic Control Estimator for Disaggregated Data

(preliminary and incomplete)

October 3, 2018

Abstract

Synthetic control methods are commonly applied in empirical research to estimate the effects of treatments or interventions of interest on aggregate outcomes. A synthetic control estimator compares the outcome of a treated unit — that is, a unit exposed to the intervention of interest — to the outcome of a weighted average of untreated units that best resembles the characteristics of the treated unit before the intervention. When disaggregated data are available, constructing separate synthetic controls for each treated unit may help avoid interpolation biases. However, the problem of finding a synthetic control that best reproduces the characteristics of a treated unit may not have a unique solution. Multiplicity of solutions is a particularly daunting challenge in settings with disaggregated data, that is, when the sample includes many treated and untreated units. To address this challenge, we propose a synthetic control estimator that penalizes the pairwise discrepancies between the characteristics of the treated units and the characteristics of the units that contribute to their synthetic controls. The penalization parameter trades off pairwise matching discrepancies with respect to the characteristics of each unit in the synthetic control against matching discrepancies with respect to the characteristics of the synthetic control unit as a whole. We study the properties of this estimator and propose data driven choices of the penalization parameter.
1. Introduction

Synthetic control methods (Abadie and Gardeazabal, 2003; Abadie et al., 2010, 2015; Doudchenko and Imbens, 2016) are often applied to estimate the treatment effects of aggregate interventions (see, e.g., Kleven et al., 2013; Bohn et al., 2014; Hackmann et al., 2015; Cunningham and Shah, 2018). Suppose we observe data for a unit that is affected by the treatment or intervention of interest, as well as data on a donor pool, that is, a set of untreated units that are available to approximate the outcome that would have been observed for the treated unit in the absence of the intervention. The idea behind synthetic controls is to match each unit exposed to the intervention or treatment of interest to a weighted average of the units in the donor pool that most closely resembles the characteristics of the treated unit before the intervention. Once a suitable synthetic control is selected, differences in outcomes between the treated unit and the synthetic control are taken as estimates of the effect of the treatment on the unit exposed to the intervention of interest.

The synthetic control method is akin to nearest neighbor matching estimators (Dehejia and Wahba, 2002; Abadie and Imbens, 2006; Imbens and Rubin, 2015) but departs from traditional matching methods in two important aspects. First, the synthetic control method does not impose a fixed number of matches for every treated unit. Second, instead of using a simple average of the matched units with equal weights, the synthetic control method matches each treated unit to a weighted average of untreated units with weights calculated to minimize the discrepancies between the treated unit and the synthetic control in the values of the matching variables. Synthetic control estimators retain, however, appealing properties of nearest neighbor matching estimators, in particular sparsity, non-negativity of the weights, and weights that sum to one. Like for nearest neighbor matching estimators, most of the synthetic control weights are equal to zero and a small number of untreated units contribute positive weights to reproduce the counterfactual of each treated observation without the treatment. Sparsity and non-negativity of the weights, along with the fact that synthetic control weights sum to one and define a weighted average, are important features that allow incorporating expert knowledge to evaluate and interpret the estimated counterfactuals (see
Abadie et al., 2015). As shown in Abadie et al. (2015), similar to the synthetic control estimator, a regression-based estimator of the counterfactual of interest – i.e., the outcome for the treated in the absence of an intervention – implicitly uses a linear combination of outcomes for the untreated with weights that sum to one. However, unlike synthetic control weights, regression weights are not explicit in the outcome the procedure, they are not sparse, and they can be negative or greater than one, allowing unchecked extrapolation outside the support of the data and complicating the interpretation of the estimate and the nature of the implicit comparison. While most applications of the synthetic control framework have focused on cases where only one or a few aggregate units are exposed to the intervention of interest, the method has found recent applications in contexts with disaggregated data, where samples contain large numbers of treated and untreated units, and the interest lies on the average effect of the treatment among the treated (see, e.g., Acemoglu et al., 2016; Gobillon and Magnac, 2016; Kreif et al., 2016). In such settings, one could simply construct a synthetic control for an aggregate of all treated units. However, interpolation biases may be much smaller if the estimator of the aggregate outcome that would have been observed for the treated in the absence of the treatment is based on the aggregation of multiple synthetic controls, one for each treated unit.

Using synthetic controls to estimate treatment effects with disaggregated data creates some practical challenges. In particular, when the values of the matching variables for a treated unit fall in the convex hull of the corresponding values for the donor pool, it may be possible to find multiple convex combinations of untreated units that perfectly reproduce the values of the matching variables for the treated observation. That is, the best synthetic control may not be unique. One practical consequence of the curse of dimensionality is that each particular treated unit is unlikely to fall in the convex hull of the untreated units, especially if the number of untreated units is small. As a result, lack of uniqueness is not often a problem in settings with one or a small number of treated units and, if it arises, it can typically be solved by ad-hoc methods, like increasing the number of covariates or by restricting the donor pool to units that are similar to the treated units. In settings with
many treated and many untreated units, non-uniqueness may be an important consideration and a problem which is harder to solve.

More generally, in contrast to common aggregate data settings with a small donor pool (see, e.g., Abadie and Gardeazabal, 2003; Abadie et al., 2010), a large number of units in the donor pool creates a setting where single untreated units may provide close matches to the treated units in the sample. Therefore, in such a setting the researcher faces a trade-off between minimizing the covariate discrepancy between each treated unit and its synthetic control as a whole (pure synthetic control case) and minimizing the covariate discrepancy between each treated unit and each unit that contributes to its synthetic control (pure matching case).

This paper provides a generalized synthetic control framework for estimation and inference. The framework builds on synthetic controls and introduces a penalization parameter that trades off pairwise matching discrepancies with respect to the characteristics of each unit in the synthetic control against matching discrepancies with respect to the characteristics of the synthetic control unit as a whole. This type of penalization is aimed to reduce interpolation biases by prioritizing inclusion in the synthetic control of units that are close to the treated in the space of matching variables. Moreover, it can be shown that as long as the penalization parameter is positive, the generalized synthetic control estimator is unique and sparse. If the value of the penalization parameter is close to zero, our procedure selects the synthetic control that minimizes the sum of pairwise matching discrepancies (among the synthetic controls that best reproduce the characteristic of the treated units). If the value of the penalization parameter is large, our estimator coincides with the pair-matching estimator. We study the formal properties of the penalized synthetic control estimator and propose data driven choices of the penalization parameter.

Our approach belongs to the recent literature on “machine learning” estimators for program evaluation problems. Following Doudchenko and Imbens (2016) which represents synthetic controls as a solution to complete an outcome matrix with missing entries, Athey et al. (2017) assumes an underlying sparse factor structure for the outcome under no treatment
and adapts matrix completion techniques to estimate a counterfactual. Their estimator penalizes the complexity of the factor structure, while our approach penalizes the discrepancy between the treated unit and each control unit that enters the synthetic unit.

2. Penalized Synthetic Control

2.1. Synthetic Control for Disaggregated Data

We code treatment using a binary variable, $D$, so $D = 1$ for treated individuals and $D = 0$ otherwise. To define the object of interest we adopt the potential outcome notation in Rubin (1974). Let $Y_1$ and $Y_0$ be random variables representing potential outcomes under treatment and under no treatment, respectively. The treatment effect is $Y_1 - Y_0$. Realized outcomes are defined as

$$Y = \begin{cases} Y_1 & \text{if } D = 1, \\ Y_0 & \text{if } D = 0. \end{cases}$$

Let $X$ be a $(p \times 1)$-vector of pre-treatment predictors of $Y_0$. Consider the distributions of the triple $(Y_1, Y_0, X)$ under treatment and no treatment, with $E[\cdot|D = 1]$ and $E[\cdot|D = 0]$ denoting the corresponding expectation operators, and $E[\cdot|X, D = 1]$ and $E[\cdot|X, D = 0]$ denoting expectations conditional on $X$. Let $P_1$ and $P_0$ be the probability measures that describe the distribution of $X$ for treated and nontreated, respectively.

**Assumption 1 (Sampling)** \{(Y_{1i}, X_i)\}_{i=1,\ldots,n_1} are $n_1$ independent draws from the distribution of $(Y_1, X)$ and \{(Y_{0i}, X_i)\}_{i=n_1+1,\ldots,n} are $n_0$ independent draws from the distribution of $(Y_0, X)$.

Combining data for treated and nontreated we obtain the pooled sample, \{(Y_i, D_i, X_i)\}_{i=1}^n, $n = n_0 + n_1$. To simplify notation, we reorder the observations in the sample so that the $n_1$ treated observations are first and the $n_0$ untreated observations are last. The quantity of interest is the average treatment effect on the treated (ATET):

$$\tau = E[Y_1 - Y_0|D = 1].$$

**Assumption 2 (Nested support)** $P_1 \ll P_0$, that is, $P_1$ is absolutely continuous with respect to $P_0$. 

4
Assumption 3 (Unconfoundedness I) \( E[Y_0|X, D = 1] = E[Y_0|X, D = 0] \).

Versions of assumptions 2 and 3 are ubiquitous in the program evaluation literature (see, e.g., Imbens, 2004). Assumption 2 states that there is no value of \( X \) for which individuals are always treated. In other words, for any treated, it should be possible to find a non-treated with the same value of the covariates in the population. Assumption 3 states that conditionally on a set of observed covariates or confounding factors, \( X \), the expected potential outcome without the treatment is the same for treated and control individuals. Graphical causal structures that support Assumption 3 are studied in Pearl (2000) and the subsequent literature.

Notice that, under these two assumptions, the counterfactual \( E[Y_0|D = 1] \) can be expressed as a weighted average of the outcome among the untreated,

\[
\tau = E[Y|D = 1] - E[VY|D = 0],
\]

where \( V = dP_1/dP_0 \). Many econometric estimators of \( \tau \) based on Assumptions 2 and 3, whether explicitly or implicitly, employ a sample analog of equation (2),

\[
\frac{1}{n_1} \sum_{i=1}^{n} Y_i D_i - \frac{1}{n_0} \sum_{i=1}^{n} Y_i (1 - D_i) V_i.
\]

Popular estimators of this type in micro-econometrics include most notably regression (Angrist and Pischke, 2008; Abadie et al., 2015), propensity score weighting (Rosenbaum and Rubin, 1983; Hirano et al., 2003) and matching (Smith and Todd, 2005). For example, in the case of the pair-matching estimator, the weight \( V_i \) given to control unit \( i \) is equal to an integer counting the number of times control unit \( i \) is the nearest neighbor of a treated unit, rescaled by \( n_0/n_1 \). The synthetic control method (Abadie and Gardeazabal, 2003; Abadie et al., 2010, 2015; Doudchenko and Imbens, 2016) also belongs to this class of estimators. It matches each treated unit to a “synthetic control”, that is, a weighted average of untreated units with weights chosen to make the values of the predictors of the outcome variable of each synthetic control closely match the values of the same predictors for the corresponding treated units.
While these assumptions are enough to recover the average treatment effect in equation (1), identification of a wide variety of parameters can be attained by strengthening the identifying conditions as in Assumptions 2’ and 3’ below.

**Assumption 2’ (Common support)** $P_1 \ll P_0$ and $P_0 \ll P_1$.

**Assumption 3’ (Unconfoundedness II)** $Y_1, Y_0 \indep D | X$.

Parameters identified by the addition of Assumptions 2’ and 3’ include quantile treatment effects, that is, differences in the quantiles of the distributions of potential outcomes (Firpo, 2007), bounds on the distribution of the treatment effect (Firpo and Ridder, 2008), or counterfactual distributions (Chernozhukov et al., 2013), among others. They also include parameters describing conditional features of the distribution of potential outcomes (see, e.g., Crump et al., 2008) and regression parameters obtained after imposing the same distribution of $X$ for treated and non-treated (Ho et al., 2007; Abadie and Spiess, 2016). While, for the sake of clarity, this article focuses on the estimation of average treatment effects, the generalized synthetic control method outlined here can be applied to estimate any of the parameters above. Moreover, Assumptions 1-3, which are adopted here for simplicity, are not the only possible identification conditions in a synthetic control setting, nor necessarily the least restrictive ones. In particular, Abadie et al. (2010) show that under a factor-structure condition on the regression residual of the outcome on the covariates for the untreated, using synthetic controls that match pre-treatment outcomes for the treated help control for unobserved confounding that arises from heterogeneity in the factor loadings.

For any $(p \times 1)$ real vector $X$ and any $(p \times p)$ real symmetric positive-definite matrix $\Gamma$, define the norm $\|X\| = (X^\Gamma X)^{1/2}$. Because $\Gamma$ is diagonalizable with strictly positive eigenvalues, we can always transform the vector $X$ so that the matrix $\Gamma$ becomes the $(p \times p)$ identity matrix. As a result, without loss of generality, we will consider only $\Gamma = I$. In the synthetic control framework, model selection – that is, the choice of the variables included in $X$ – is operationalized through the choice $\Gamma$, which rescales or weights each predictor in $X$ according to its predictive power on the outcome (see Abadie et al., 2010). In a setting
with many treated and untreated units, the standard synthetic control estimation procedure is as follows:

1. For each treated unit, \(i = 1, \ldots, n_1\), compute the \(n_0\)-vector of weights \(W_i^* = (W_{i,n_1+1}', \ldots, W_{i,n}')\) that solves

\[
\begin{align*}
\min_{W_i \in \mathbb{R}^{n_0}} & \quad \left\| X_i - \sum_{j=n_1+1}^{n} W_{i,j}X_j \right\|^2 \\
\text{s.t.} & \quad W_{i,n_1+1} \geq 0, \ldots, W_{i,n} \geq 0, \\
& \quad \sum_{j=n_1+1}^{n} W_{i,j} = 1,
\end{align*}
\]

where \(W_{i,j}^*\) is the weight given to control unit \(j\) in the synthetic control unit corresponding to treated unit \(i\).

2. Estimate \(\tau\) using the mean difference between the realized outcome and the synthetic outcome for the treated

\[
\hat{\tau} = \frac{1}{n_1} \sum_{i=1}^{n_1} \left[ Y_i - \sum_{j=n_1+1}^{n} W_{i,j}^* Y_j \right],
\]

Notice that \(\hat{\tau}\) is the estimator in equation (3) reweighting each nontreated unit, \(j = n_1 + 1, \ldots, n\), by \(V_j = (n_0/n_1)S_j\), where \(S_j = \sum_{i=1}^{n_1} W_{i,j}^*\) is the sum of the synthetic control weights assigned to unit \(j\). Lemma A.2 in the appendix derives some properties of \(S_j\).

While, to simplify notation, we described here a cross-sectional setting only, the extension to the more common panel data setting for synthetic controls is immediate and we will use it later.

Notice that, when \(X_i\) belongs to the convex hull of \(\{X_{n_1+1}, \ldots, X_n\}\), the value of the objective function (4) at the minimum is equal to zero and multiple solutions may exist. By Carathéodory’s theorem, a solution with at most \(p + 1\) non-zero weights exists in that case. On the other hand, it is easy to show that if \(X_i\) does not belong to the convex hull of \(\{X_{n_1+1}, \ldots, X_n\}\) and under weak regularity conditions (that is, if observations are in “general position”) the solution is unique and involves at most \(p + 1\) non-zero weights, see Theorem 1 below.
2.2. Penalized Synthetic Control

The main contribution of this article is to propose an alternative, penalized version of the synthetic control estimator in equation (4). For treated unit \( i \) and given a positive constant \( \lambda \), the penalized synthetic control weights, \( W^*_i(\lambda) \), solve

\[
\min_{W_i \in \mathbb{R}^{n_0}} \left\| X_i - \sum_{j=n_1+1}^n W_{i,j}X_j \right\|^2 + \lambda \sum_{j=n_1+1}^n W_{i,j} \| X_i - X_j \|^2
\]

s.t. \( W_{i,n_1+1} \geq 0, \ldots, W_{i,n} \geq 0, \)

\[
\sum_{j=n_1+1}^n W_{i,j} = 1.
\]

The penalized synthetic control estimator is then given by

\[
\hat{\tau}(\lambda) = \frac{1}{n_1} \sum_{i=1}^{n_1} Y_i - \sum_{j=n_1+1}^n W^*_i(\lambda)Y_j.
\]

The tuning parameter \( \lambda \) sets the trade-off between componentwise and aggregate fit. The choice of the value of \( \lambda \) is important and will be discussed in Section 3. The penalized synthetic control estimator encompasses both the synthetic control estimator and the nearest-neighbor matching as special polar cases. At one end of the spectrum, as \( \lambda \to 0 \), the penalized estimator becomes the synthetic control that minimizes the sum of pairwise matching discrepancies among the set of synthetic controls that best reproduce the characteristics of the treated units. Our motivation to choose among synthetic controls that fit the treated unit equally well by minimizing the sum of pairwise matching discrepancies is to reduce worst-case interpolations biases. At the other end of the spectrum, as \( \lambda \to \infty \), the penalized estimator becomes the one-match nearest-neighbor matching with replacement estimator in Abadie and Imbens (2006).

Let \( X_0 \) be the \((p \times n_0)\) matrix with column \( j \) equal to \( X_{n_1+j} \), and let \( \Delta_i \) be the \((n_0 \times 1)\) vector with \( j\)-th element equal to \( \| X_i - X_{n_1+j} \|^2 \). Moreover, let \( \Delta_i^{NN} = \min_{j=1,\ldots,n_0} \| X_i - X_{n_1+j} \|^2 \), be the smallest discrepancy between unit \( i \) and the units in the donor pool. Finally, let \( W^*_i(\lambda) \) be a solution to (6), and \( \Delta^*_i(\lambda) = \| X_i - X_0W^*_i(\lambda) \|^2 \) be the square of the discrepancy between unit \( i \) and the (penalized) synthetic control.
Lemma 1 (Discrepancy Bounds) For any $\lambda \geq 0$

$$0 \leq \Delta^*_i(\lambda) \leq \Delta^{NN}_i,$$

and for $\lambda > 0$

$$\Delta^{NN}_i \leq \Delta'_i W^*_i(\lambda) \leq \frac{1 + \lambda}{\lambda} \Delta^{NN}_i.$$

The first inequality states that the synthetic unit is contained in a closed ball of center $X_i$ and radius equal to the distance to the nearest-neighbor, $\sqrt{\Delta^{NN}_i}$. The second inequality shows that the tuning parameter $\lambda$ controls the compound discrepancy between the treated unit and the units that contribute to the synthetic control, $\Delta'_i W^*_i(\lambda)$. All proofs are in the appendix.

Some remarks are in order to justify the choice of the penalization term in equation (6). First, notice that the penalty term is linear rather than quadratic in the weights. This has the advantage of producing easy-to-interpret sparse solutions, similarly to a matching procedure.

Notice also that the optimization problem in (6) can be solved via quadratic programming, like the standard synthetic control in (5). To see why notice that, in matrix notation, program (6) is

$$\min_{W \in \mathbb{R}^{n_0}} (X_i - X_0 W)' (X_i - X_0 W) + \lambda \Delta'_i W$$

s.t. $1_{n_0}' W = 1, W \geq 0,$

where $1_{n_0}$ is the $(n_0 \times 1)$ vector of ones and the inequality restriction applies to each component of $W$.

A third remark has to do with uniqueness of the solution. In the absence of the penalty term (that is, when $\lambda = 0$), the problem in (6) and (8) can be solved by projecting $X_i$ on the convex hull of $X_0$. Existence of sparse solutions follows from Carathéodory’s theorem. However, if $\lambda = 0$ the solution to the problem in (6) and (8) may not be unique, especially if $X_i$ belongs to the convex hull of the columns of $X_0$. Adopting $\lambda > 0$ penalizes solutions with potentially large interpolation biases created by large matching discrepancies and produces uniqueness and sparsity as stated in the following result.
Theorem 1 (Uniqueness and Sparsity) Suppose (i) \( \lambda > 0 \); (ii) any submatrix of \( X'_0 \) consisting of no more than \( p \) rows has full row rank; (iii) \( 1_{p+1} \) does not belong to the column space of any submatrix of \( X'_0 \) consisting of \( p+1 \) rows; (iv) any submatrix composed by \( p+2 \) or more rows of \( (X'_0 \ 1_{n_0} \Delta_i) \) has full column rank. Then, the optimization problem in equation (6) admits a unique solution \( W^*_i(\lambda) \) with at most \( p+1 \) non-zero components.

Condition (i) imposes a non-zero penalization on the compound discrepancy. Condition (ii) implies that any subset of \( p \) or fewer control observations are not linearly dependent in the values of the predictors. Conditions (iii) and (iv) require that there is no subset of \( p+1 \) or more control observations with values of the predictors that fall in a lower-dimensional affine subspace. In addition, condition (iv) requires that there is no set of control units of cardinality \( p+2 \) or larger such that the values of the predictors belong to a sphere with center at \( X_i \).

Example: Consider a simple numerical example with only one covariate. Suppose, there is one treated unit with \( X_1 = 2 \) and three control units with \( X_2 = 1, \ X_3 = 4 \) and \( X_4 = 5 \). This simple setting is depicted in Figure 1.

Figure 1: A simple example

\[
\begin{array}{cccc}
X_2 & X_1 & X_3 & X_4 \\
\bullet & \circ & \bullet & \circ \\
1 & 2 & 3 & 4 & 5
\end{array}
\]

Notice that \( X_1 \) belongs to \([1,5]\), the convex hull of the columns of \( X_0 \). Consider first the case with \( \lambda = 0 \). Then, \( W^*(0) = (2/3 \quad 1/3 \quad 0)' \) and \( W^{**}(0) = (3/4 \quad 0 \quad 1/4)' \) are the only two sparse solutions (with number of non-zero weights not greater than \( p+1 = 2 \)) to (6). The first sparse solution, \( W^*(0) \), interpolates \( X_1 = 2 \) using \( X_2 = 1 \) and \( X_3 = 4 \). The second sparse solution, \( W^{**}(0) \) is of lower quality relative to \( W^*(0) \) in terms of compound discrepancy, as it uses an interpolation scheme that replaces \( X_3 \) with \( X_4 \), an observation farther away from \( X_1 \). As a result, \( W^*(0) \) is preferred over \( W^{**}(0) \) in terms of worst case interpolation bias (e.g., under a Lipschitz bound on \( E[Y|X,W = 0] \)). However, the better compound fit of \( W^*(0) \) is not reflected in a better value in the objective function in (4). Moreover,
because any convex combination of $W^*(0)$ and $W^{**}(0)$ is also a solution, the program in (4) has an infinite number of solutions, $\mathcal{W}_0^* = \{aW^*(0) + (1-a)W^{**}(0): a \in [0,1]\}$. Let $\tilde{V}(a) = aW^*(0) + (1-a)W^{**}(0)$. The compound discrepancy of $\tilde{V}(a)$ is

$$\Delta_i\tilde{V}(a) = 3 - a.$$

From Figure 1, it is apparent that $W^*(0)$, which is obtained making $a = 1$, produces the lowest compound discrepancy among all the solutions to equation (4).

When $\lambda > 0$, however, the program (6) has a unique solution, which is sparse:

$$W^*(\lambda) = \begin{cases} (2 + \lambda/2 \ 1 - \lambda/2 \ 0)'/3 & \text{if } 0 < \lambda \leq 2, \\ (1 \ 0 \ 0)' & \text{if } \lambda > 2. \end{cases}$$

Notice that $W^*(\lambda)$ never puts any weight on $X_4$. As $\lambda \to \infty$, $W^*(\lambda)$ selects the nearest-neighbor match, and as $\lambda \to 0$, $W^*(\lambda)$ converges to $W^*(0)$, the (non-penalized) synthetic control in $\mathcal{W}_0^*$ with the smallest compound discrepancy. □

Next theorem provides a characterization of the units contributing to a particular synthetic control, $X_0W^*_i(\lambda)$ with $\lambda > 0$, as vertices of the face of the Delaunay complex containing $X_0W^*_i(\lambda)$ in the Delaunay tessellation of $X_{n_1+1}, \ldots, X_n$.

**Theorem 2 (Delaunay Property)** Let $W^*_i(\lambda)$ be a solution to the penalized synthetic control problem in (6) with $\lambda > 0$. Consider the Delaunay tessellation induced by the columns of $X_0$. Then, for any control unit $j = n_1+1, \ldots, n$, such that $X_j$ is not a vertex of face of the Delaunay complex containing $X_0W^*_i(\lambda)$ it holds that $W^*_{i,j}(\lambda) = 0$.

This result along with the first part of Lemma 1, which bounds $\|X_i - X_0W^*_i(\lambda)\|$, provides a notion of proximity between each treated unit $X_i$ and the untreated units that contribute to its synthetic control. Theorem 2 provides also a simple way to compute the solution for the “pure synthetic control case” ($\lambda \to 0$) that does not entail the choice of an arbitrarily small value of $\lambda$ to use in (6). Recall that when $\lambda = 0$, the problem of minimizing $\|X_i - X_0W\|$ subject to the weight constraints may have multiple (infinite) number of solutions, in which case $X_i = X_0W$ for all solutions. In the presence of multiple solutions, the “pure synthetic control case” selects the solution that produces the lowest compound discrepancy, $W'\Delta_i$,.
among all $W$ such that $X_i = X_0W$. Directly solving (6) for an arbitrarily small value of $\lambda$ requires, in practice, a choice for $\lambda$. It also creates computational difficulties, as the minimization problem is close to one with multiple solutions and the dimension of $W$ may be large. Theorem 2 implies that the solution of (6) for $\lambda \to 0$ assigns positive weights only to the vertices of the simplex in the Delaunay tessellation of $X_{n_1+1}, \ldots, X_n$ that contains the projection of $X_i$ on the convex hull of the columns of $X_0$.

2.3. Bias-Corrected Synthetic Control

We will also consider bias-corrected versions of synthetic control estimator. We adopt a bias correction analogous to that implemented in Abadie and Imbens (2011) for matching estimators. Let $\mu_0(x) = E[Y|X = x, D = 0]$, and let $\hat{\mu}_0(x)$ be an estimator of $\mu_0(x)$. A bias-corrected version of the synthetic control estimator in equation (7) is

$$
\hat{\tau}_{BC}(\lambda) = \frac{1}{n_1} \sum_{i=1}^{n_1} \left[ (Y_i - \hat{\mu}_0(X_i)) - \sum_{j=n_1+1}^{n} W_{i,j}^*(\lambda)(Y_j - \hat{\mu}_0(X_j)) \right].
$$

(9)

3. Penalty Choice

In this section we present two data-driven selectors for the penalty term, $\lambda$. In the context of treatment effects estimation, cross-validation (CV) is complicated by the absence of data on a “ground truth” (that is, on the values of $Y_0$ for the treated units in the post-intervention periods, see Athey and Imbens, 2016). The first selector proposed in this section is based on cross-validation on the outcomes on the untreated units in the post-intervention period. The second selector uses a strategy similar to the model selection procedure in Abadie et al. (2015), minimizing mean squared prediction error (MSPE) in a hold-out pre-intervention period.

3.1. Leave-One-Out Cross-Validation of Post-Intervention Outcomes for the Untreated

This section discusses a leave-one-out cross-validation procedure to find an optimal value $\lambda$ by minimizing mean squared prediction error for the untreated units in the post-intervention period.
period. Consider a balanced panel data setting with $T$ periods and $T_0 < T$ pre-intervention periods. Let $Y_{it}$ be the outcome for unit $i$ at time $t$. The procedure is as follows:

1. For each control unit $i = n_1 + 1, \ldots, n$, and each post-intervention period, $t = T_0 + 1, \ldots, T$, calculate

$$\hat{\tau}_{it}(\lambda) = Y_{it} - \sum_{j=n_1+1}^{n} W_{i,j}^*(\lambda)Y_{jt},$$

where $W_{i,j}^*(\lambda)$ is a synthetic control for unit $i$ that is produced by the donor pool $\{n_1 + 1, \ldots, n\}\{i\}$.

2. Choose $\lambda$ to minimize some measure of loss, such as the mean squared prediction error for the individual outcomes,

$$\frac{1}{n_0(T - T_0)} \sum_{i=1}^{n_0} \sum_{t=T_0+1}^{T} \left(\hat{\tau}_{it}(\lambda)\right)^2.$$

3.2. Pre-Intervention Holdout Validation on the Outcomes of the Treated

An alternative selector of $\lambda$ is based on validation over the outcomes for the treated on a hold out pre-intervention period. This is similar in spirit to the model selection procedure in Abadie et al. (2015). To simplify the exposition and because it is the most natural choice, we will assume that the validation period is at the end of the pre-intervention period, although other choices are possible. The procedure is as follows:

1. Split the pre-intervention period that contains $T_0$ dates into $T_0 - k$ initial training dates and $k$ subsequent validation dates.

2. For each treated individual, $i$, and validation period, $t \in \{T_0 - k, \ldots, T_0\}$, compute

$$\hat{\tau}_{it}(\lambda) = Y_{it} - \sum_{j=n_1+1}^{n} W_{i,j}^*(\lambda)Y_{jt},$$

where $W_{i,j}^*$ solve (6) with $X$ measured in the training period.
3. Choose $\lambda$ to minimize some measure of error, such as the sum of the squared prediction for the individual outcomes,

$$
\sum_{i=1}^{n_1} \sum_{t=T_0-k}^{T_0} \left( \hat{\tau}_{it}(\lambda) \right)^2,
$$

or the squared prediction error of the aggregate outcomes,

$$
\sum_{t=T_0-k}^{T_0} \left( \sum_{i=1}^{n_1} \hat{\tau}_{it}(\lambda) \right)^2.
$$

Notice that the cross-validation procedures delineated can also be applied here to guide model selection (i.e., choice of $V$) as in Abadie et al. (2015).

4. **Inference**

In this section, we adapt the inferential framework in Abadie et al. (2010) to the penalized synthetic control estimators of section 2. Like in Abadie et al. (2010), our inferential exercises compare the value of a test statistic to its permutation distribution induced by random reassignment of the treatment variable in the data set. We next describe three possible implementations that employ different test statistics and permutation schemes. Alternative test statistics and permutation schemes are possible and, in practice, the choice among them should take into account the nature of the parameter(s) of interest (e.g., individual vs. aggregate effects), the characteristics of the intervention that is the object of the analysis and the structure of the data set. Randomized reassignment of the treatment in the data is taken here as a benchmark against which we evaluate the rareness of the sample value of a test statistic, and may not reflect the actual and typically unknown treatment assignment process (see Abadie et al., 2010, 2015). Firpo and Possebom (2018) propose a procedure to assess the sensitivity of permutation inference to deviations from the reassignment benchmark.

4.1. **Inference on Aggregate Effects**

Here we outline a simple permutation procedure that employs test statistic, $\hat{T}$, that measures aggregate effects for the treated. Examples of aggregate statistics of this type are the synthetic controls estimators in equations (7) and (9). Similar to Abadie et al. (2010), in a
panel data setting $\hat{T}$ can be based on the ratio between the aggregate mean square prediction error in a post-intervention period $T_i \subseteq \{T_0 + 1, \ldots, T\}$ and a pre-intervention period $T_0 \subseteq \{1, \ldots, T_0\}$,

$$\sum_{t \in T_0} \left( \sum_{i=1}^{n_1} \hat{\tau}_{it}(\lambda) \right)^2 / \sum_{t \in T_i} \left( \sum_{i=1}^{n_1} \hat{\tau}_{it}(\lambda) \right)^2. \quad (10)$$

Let $D^{obs} = (D_1, \ldots, D_n)$ be the observed treatment assignment. We will write $\hat{T}(D^{obs})$ to indicate the value of the test statistic for the sample at hand, and $\hat{T}(D)$ to indicate the value of the test statistics when the treatment values are reassigned as in $D$ in the data. The test is as follows:

1. Compute the treatment effect estimate in the original sample $\hat{T}(D^{obs})$.

2. At each iteration, $b = 1, \ldots, B$, permute at random the components of $D^{obs}$ to obtain $\hat{T}(D^{(b)})$.

3. Calculate $p$-values as the frequency across iterations of values of $\hat{T}(D^{(b)})$ more extreme than $\hat{T}(D^{obs})$. Typically, for two-sided tests:

$$\hat{p} = \frac{1}{B + 1} \left( 1 + \sum_{b=1}^{B} 1 \left\{ |\hat{T}(D^{(b)})| \geq |\hat{T}(D^{obs})| \right\} \right).$$

For one sided tests:

$$\hat{p} = \frac{1}{B + 1} \left( 1 + \sum_{b=1}^{B} 1 \left\{ \hat{T}(D^{(b)}) \geq \hat{T}(D^{obs}) \right\} \right),$$

or

$$\hat{p} = \frac{1}{B + 1} \left( 1 + \sum_{b=1}^{B} 1 \left\{ \hat{T}(D^{(b)}) \leq \hat{T}(D^{obs}) \right\} \right).$$

4.2. Inference Based on the Sum of Rank Statistics of Unit-Level Treatment Effects Estimates

Similar to Dube and Zipperer (2015), we propose a test based on the rank statistics of the unit-level treatment effects. Unlike the test in Dube and Zipperer (2015), we calculate the permutation distribution directly from the data. The test we employ is based on the sum of
ranks of individual treatment effects in the ordered sample combining the \( n_1 \times (B + 1) \) unit-level treatment effects for the actual assignments and \( B \) random permutations. Individual treatment effects, \( \hat{T}_i \), may be based on differences in outcomes between treated and synthetic controls,

\[
Y_i - \sum_{j=n_1+1}^{n} W_{i,j}^*(\lambda)Y_j,
\]

bias corrected versions of the unit-level treatment effects,

\[
(Y_i - \hat{\mu}_0(X_i)) - \left( \sum_{j=n_1+1}^{n} W_{i,j}^*(\lambda)Y_j - \hat{\mu}_0(X_j) \right),
\]

or unit-level versions of the mean squared prediction error ratio in equation (10). The test is implemented as follows:

1. Compute unit-level measures treatment effects for the treated, \( \hat{T}_i \) for \( i = 1, \ldots, n_1 \), under the actual treatment assignment, \( D_{\text{obs}} \).

2. At each iteration \( b = 1, \ldots, B \), permute at random the components of \( D_{\text{obs}} \) to obtain treatment effects \( \hat{T}_i(D^{(b)}) \) for the treated. Denote these estimates \( \hat{T}_1^{(b)}, \ldots, \hat{T}_{n_1}^{(b)} \) (in arbitrary order).

3. Calculate the ranks \( R_1, \ldots, R_{n_1}, R_1^{(1)}, \ldots, R_{n_1}^{(1)}, \ldots, R_1^{(B)}, \ldots, R_{n_1}^{(B)} \) associated to the \( n_1 \times (B + 1) \) individual treatment effect estimates \( \hat{T}_1, \ldots, \hat{T}_{n_1}, \hat{T}_1^{(1)}, \ldots, \hat{T}_{n_1}^{(1)}, \ldots, \hat{T}_1^{(B)}, \ldots, \hat{T}_{n_1}^{(B)} \) (or of their absolute values or negative values) and the sums of ranks for each permutation, \( SR = \sum_{i=1}^{n_1} R_i, SR^{(b)} = \sum_{i=1}^{n_1} R_i^{(b)} \), \( b = 1, \ldots, B \).

4. Calculate \( p \)-values as:

\[
\hat{p} = \frac{1}{B + 1} \left( 1 + \sum_{b=1}^{B} 1 \left\{ SR^{(b)} \geq SR \right\} \right).
\]

5. **Monte Carlo Experiment**

We report the results of a Monte Carlo experiment that investigates the finite sample properties of the penalized synthetic control estimator relative to its unpenalized version \( (\lambda = 0) \) and to the (nearest-neighbor) matching estimator in a panel data framework.
Irrespective of the treatment status, the outcome at time \( t \in \{1, 2\} \) is generated by 
\[
Y_{i,t} = \left( \sum_{j=1}^{p} X_{i,j}^r \right) / \beta + \varepsilon_{i,t} \text{ with } r \text{ a positive real governing the degree of linearity of the outcome function. For any } t, \varepsilon_{i,t} \perp \perp X_i \text{ and } \varepsilon_{i,t} \sim \mathcal{N}(0,1). \]
For the \( n_1 \) treated units, \( X_i \), is a vector of dimension \( p \) with iid entries distributed as \( U[a,b] \), with \( a,b > 0 \). For the \( n_0 \) control units, \( X_i \) is a vector of the same dimension with iid entries distributed according to 
\[
density \frac{2x}{b-a+2h} \mathbf{1}\{a-h < x < b+h\} \text{ with } h > 0, \text{ i.e. each entry has the same distribution as } \sqrt{U} \text{ where } U \sim \mathcal{U}[a-h,b+h]. \]
The larger the parameter \( h \), the smaller the support of the treated relative to that of the controls.
\( \beta \) is a constant set so that \( \beta^2 = V \left( \sum_{j=1}^{p} X_{i,j}^r | D_i = 1 \right) \)
\[
\beta = \sqrt{p} \sqrt{\frac{b^{2r+1} - a^{2r+1}}{(b-a)(2r+1)} - \left( \frac{b^{r+1} - a^{r+1}}{(b-a)(r+1)} \right)^2}. \]
As a consequence \( V(Y_{i,t} | D_i = 1) = 2 \) and the signal-to-noise ratio for the treated is equal to one.

We compare the performances of synthetic control and matching estimators. Both procedures have a tuning parameter, \( \lambda \) for the synthetic control and the number of neighbors \( M \) for matching. We will consider these two estimators with a fixed and a data-driven choices of tuning parameter. Under the fixed procedure, \( \lambda \to 0 \) in the synthetic control and \( M = 1 \) in the matching estimator, encompassing both polar cases of the penalized synthetic control estimator highlighted in this paper. The case \( \lambda \to 0 \) is referred to as the “pure synthetic control” case that reproduces the treated as closely as possible by taking a convex combination of the vertices of the Delaunay triangle that contains the treated, when possible. Its computation is based on the remark following Theorem 2. It is not to be confused with the non-penalized synthetic control which does not take into account the compound discrepancy, for which we also report results. The data-driven choice of tuning parameter uses the first period outcome to minimize the MSE over that period. At each simulation step, both \( \lambda \) and \( M \) are chosen so as to minimize their respective criteria
\[
MSE(\lambda) = \frac{1}{n_1} \sum_{i=1}^{n_1} \left( Y_{i,1} - \sum_{j=n_1+1}^{n} W_{i,j}^*(\lambda)Y_{j,1} \right)^2,
\]
and

\[ \text{MSE}(M) = \frac{1}{n_1} \sum_{i=1}^{n_1} \left( Y_{i,1} - \frac{1}{M} \sum_{j \in J_M(i)} Y_{j,1} \right)^2, \]

where \( J_M(i) \) is the set of indices of the \( M \) control units that are the nearest to treated unit \( i \). We also report a bias-corrected version of the estimators as in Section 2.3, based on a XXX specification.

The degree of the outcome function, \( r \), is the key parameter governing the relative performances of the candidate estimators. When \( r = 1 \), the outcome function is linear, which suggests emphasizing the “synthetic control” part in (6) at the cost of a larger component-wise discrepancy, so we expect the pure synthetic control to perform well, while the 1-to-1 matching should do relatively worse, exhibiting a notably larger variance. As a consequence, the data-driven \( \lambda \) is likely to be small and the penalized synthetic control is likely to perform similarly as the pure synthetic control. As \( r \) increases, the synthetic control with \( \lambda \to 0 \) should suffer from a larger interpolation bias, while the performance of the 1-to-1 matching should improve. As a consequence, the data-driven \( \lambda \) is expected to increase so that the penalized synthetic control strikes a favorable compromise in the bias-variance trade-off.

Results are reported in Tables 1, 2 and 3 for \( n_0 = 20, 40, 100 \) respectively. For each configuration and each estimator \( \hat{\tau} \), we report four statistics computed on the treated sample in the second period. The first is the individual-level Root Mean Squared Error (RMSE) defined as

\[ \frac{1}{B} \sum_{b=1}^{B} \frac{1}{n_1} \sum_{i=1}^{n_1} \left( \hat{\tau}_{i2}^{(b)} \right)^2, \]

the second is the aggregate-level RMSE

\[ \frac{1}{B} \sum_{b=1}^{B} \left( \frac{1}{n_1} \sum_{i=1}^{n_1} \hat{\tau}_{i2}^{(b)} \right)^2, \]

the third is the aggregate absolute bias

\[ \left| \frac{1}{B} \sum_{b=1}^{B} \frac{1}{n_1} \sum_{i=1}^{n_1} \hat{\tau}_{i2}^{(b)} \right|. \]
the last is the average sparsity defined as the average number of control units used in the match to a given treated unit, \textit{i.e.} number of non-zero entries in $W_i^*(\lambda)$ or number of matches in the optimized matching procedure.
Table 1: Monte-Carlo Simulations I, $n_0 = 20$

| $r = 1$ | RMSE indiv | RMSE | $|Bias|$ | Sparsity | $r = 1.2$ | RMSE indiv | RMSE | $|Bias|$ | Sparsity | $r = 1.4$ | RMSE indiv | RMSE | $|Bias|$ | Sparsity | $r = 1.8$ | RMSE indiv | RMSE | $|Bias|$ | Sparsity |

Table 4: Extended Monte-Carlo Simulations I, n = 20
6. Empirical Applications

6.1. The Value of Connections in Turbulent Times

This section revisits Acemoglu et al. (2016) on the effect of the announcement of the appointment of Tim Geithner as Treasury Secretary on November 21, 2008 on stock returns of firms that were connected to him. To choose $\lambda$ we employ the pre-intervention holdout procedure of Section 3.2. The training sample uses stock returns over a 250-day window that ends 30 days prior Geithner announcement. The validation sample to select the tuning parameter $\lambda$ uses returns on the following 30-day window. Abnormal returns are defined as the difference between a connected firm returns and its synthetic match returns. The measure of the announcement effect is the Cumulative Abnormal Returns (CAR) defined as the sum of abnormal returns since the announcement day.

Our methodology differs in a few ways from the original study. To mitigate complications caused by lack of uniqueness of the synthetic control estimator, Acemoglu et al. (2016) construct synthetic controls on the basis of pretreatment stock returns and restrict the units entering each synthetic control to the 20 untreated units with the highest correlation in returns with the treated unit during the training window. This is a clever ad-hoc solution to the non-uniqueness problem described in Section 1, but it does not easily generalize to contexts where synthetic controls are constructed on the basis of multiple characteristics, and leaves unaddressed the issue of how to decide on the maximum number of units that contribute to the synthetic controls. Instead, we use the full sample of control units and apply our penalized version of the synthetic control without this pre-selection step. Moreover, the original study re-weights the CAR of each treated by goodness-of-fit instead of using a simple average across the treated (see equation (7) in their paper). The authors argue that treated firms for which their corresponding synthetic unit fits better its returns over the pre-treatment period should be emphasized because they contain more information. While this assertion makes intuitive sense, especially for cases when a lack of common support prevents a particular treated unit from being well reproduced by a convex combination of control units, the properties of such an estimator are unknown and not covered in the
theoretical part of our work. As a consequence, we only use a simple average. Lastly, the 10% firms most correlated with Citigroup are discarded, as in the original study, to exclude the effect of the announcement of Citigroup’s bailout that could confound the effect of Geithner announcement.

Table 5 displays our results which are qualitatively similar to the original study, albeit more muted: significance is only obtained at the 5% level in the corrected inference procedure. Figure 2 displays the Geithner announcement effect on stock returns versus the Fisher distribution under the no-treatment effect assumption. With the selected penalty level of .1, we find that the median number of active controls – defined as having a positive weight in the synthetic unit – for each treated unit is 26.7 (min: 20, max: 40) which is substantially more than in the original analysis where active controls are limited to be 20 or less. Another key difference in our inference procedure is that we recompute the cross-validated optimal $\lambda^{opt}$ and corresponding synthetic control weights for every treated under the given permutation for each random permutation, as explained in Section 4. These two observations help explaining the difference between our results and the original study.

| Mean nb. of active controls | 26.7 |
| Cross-val. (RMSE) λ | 0.08 |

Note: This table displays Cumulative Abnormal Returns (CAR) on day 1 and 10 corresponding to panels B and C, columns 2 and 3, of Table 5 in Acemoglu et al. (2016). Results are obtained on their base sample which excludes the 10% firms whose returns are most correlated with Citigroup. We define being treated as at least one meeting between the firm and Geithner in 2007-08. The estimate column corresponds to the difference between the treated returns and synthetic control returns accumulated for the said number of days since announcement. The number between brackets are Fisher confidence intervals at 95% levels, based on 5,000 permutations. The quantiles displayed in the other columns are computed as quantiles of the Fisher distribution under the no-effect assumption. 20,000 random permutations have been used. Corrected inference discards permuted treated units for which the in-sample MSPE was three times larger than the mean MSPE for original treated units. Bias-corrected inference relies on a linear specification for the regression function. Asterisks denote significance levels (** = 5%, * = 10%).
Figure 2: Abnormal Returns after Geithner Announcement, non-corrected inference

Note: The confidence bands are computed as quantiles of the Fisher distribution under the no-effect assumption. They do not define a confidence interval for the treatment effect. When the solid red line goes out of these bands, it means the effect is significant. 20,000 permutations are used. The shadowed grey area is the post-announcement period.
Appendix

Proof of Lemma 1

Notice that if the first result in Lemma 1 does not hold, then $W_i^*(\lambda)$ cannot be a solution to the problem in equation (6). We start by proving the upper bound in the second inequality. Since $W_i^*(\lambda)$ minimizes (6), it follows that

$$(X_i - X_0W_i^*(\lambda))^T(X_i - X_0W_i^*(\lambda)) + \lambda\Delta_i^T W_i^*(\lambda) \leq (X_i - X_{NN,i})^T(X_i - X_{NN,i}) + \lambda\Delta_i^{NN}$$

Therefore,

$$\lambda \Delta_i^T W_i^*(\lambda) \leq (1 + \lambda)\Delta_i^{NN},$$

and the result follows from $\lambda > 0$. The lower bound follows from the definition of $\Delta_i^{NN}$. □

Proof of Theorem 1

Without loss of generality, consider the case with only one treated, $n_1 = 1$. Program (8) is

$$\min_W f_\lambda(W) = (X_1 - X_0W)'(X_1 - X_0W) + \lambda W'\Delta_1,$$

s.t. $W \in W,$

where $W = \{W \in [0,1]^{n_0} | W't_{n_0} = 1\}$. It is easy to check that the feasible set, $W$, is convex and compact. Because $f_\lambda$ is continuous and $W$ is compact, it follows that the function attains a minimum on $W$. Moreover, $X'X_0$ is positive semi-definite, so $f_\lambda$ is convex.

Suppose that more than one solution exist. In particular, assume that $W_1$ and $W_2$ are solutions, with $f_\lambda(W_1) = f_\lambda(W_2) = f_\lambda^*$. Then, for any $a \in (0,1)$ we have that $aW_1 + (1-a)W_2 \in W$. Because $f_\lambda$ is convex, we obtain

$$f_\lambda(aW_1 + (1-a)W_2) \leq af_\lambda(W_1) + (1-a)f_\lambda(W_2) = f_\lambda^*.$$

This implies that the problem has either a unique solution or infinitely many. In addition, if there are multiple solutions they all produce the same fitted values $X_0W$. To prove this suppose there are two solutions $W_1$ and $W_2$ such that $X_0W_1 \neq X_0W_2$. Then, because $\|x - c\|^2$ is strictly convex in $c$, for $a \in (0,1)$ we obtain

$$f_\lambda(aW_1 + (1-a)W_2) = \|X_1 - X_0(aW_1 + (1-a)W_2)\|^2 + \lambda(aW_1 + (1-a)W_2)'\Delta_1$$

$$< a\|X_1 - X_0W_1\|^2 + (1-a)\|X_1 - X_0W_2\|^2 + \lambda(aW_1 + (1-a)W_2)'\Delta_1$$

$$= af_\lambda^* + (1-a)f_\lambda^*$$

$$= f_\lambda^*,$$

which contradicts that $W_1$ and $W_2$ are solutions. As a result, if $W_1$ and $W_2$ are solutions, then $X_0W_1 = X_0W_2$. Moreover, now $\lambda > 0$ implies $W_1'\Delta_1 = W_2'\Delta_1$.

Karush-Kuhn-Tucker conditions imply:

$$X_j'(X_1 - X_0W) - \frac{\lambda}{2}\Delta_1j = \pi - \gamma_j$$

$$W_j \geq 0, W't_{n_0} = 1, \gamma_j \geq 0, \gamma_j W_j = 0.$$
Stacking the first \( n_0 \) conditions and pre-multiplying by \( W' \), we obtain

\[
W'X'_0(X_1 - X_0W) - \frac{\lambda}{2} W'\Delta_1 = \pi.
\]

From this equation, it follows that the value of \( \pi \) is unique across solutions, because \( X'_0W \) and \( W'\Delta_1 \) are unique across solutions. Given that \( \pi \) is unique, the equations

\[
X'_j(X_1 - X_0W) - \frac{\lambda}{2} \Delta_{1,j} = \pi - \gamma_j
\]

imply that the \( \gamma_j \)'s are unique across solutions. As a result, for any solution the subvector of \( W \) formed by the rows associated with non-zero \( \gamma_j \)'s is equal to zero. Let \( \tilde{X}_0 \) be the submatrix of \( X_0 \) formed by the columns associated with zero \( \gamma_j \)'s, and define \( \tilde{W}, \tilde{\Delta}_1 \), and \( 1_{\tilde{n}_0} \) analogously, where \( \tilde{n}_0 \) is the number of columns of \( \tilde{X}_0 \). Then,

\[
\tilde{X}_0'(X_1 - \tilde{X}_0\tilde{W}) = \frac{\lambda}{2} \tilde{\Delta}_1 + \pi 1_{\tilde{n}_0}.
\]

As an aside, notice that if \( \lambda > 0 \), then \( \|X_1 - X_0W\| = 0 \) implies that \( \tilde{\Delta}_1 \) is a constant vector. We therefore obtain that if \( \lambda > 0 \) and \( \tilde{\Delta}_1 \) is not constant, then it must be the case that \( \|X_1 - X_0W\| > 0 \).

Let \( Az = c \), where

\[
A = \left( \begin{array}{cc} \tilde{X}'_0\tilde{X}_0 & 1_{\tilde{n}_0} \\ 1'_{\tilde{n}_0} & 0 \end{array} \right), \quad z = \left( \begin{array}{c} \tilde{W} \\ \pi \end{array} \right), \quad c = \left( \begin{array}{c} \tilde{X}'_0X_1 - (\lambda/2)\tilde{\Delta}_1 \end{array} \right).
\]

Any solution to the program has to satisfy this set of linear equations, and the non-negativity constraint on \( \tilde{W} \).

Assume that any submatrix of \( X'_0 \) consisting of no more than \( p \) rows has full row rank. Suppose \( \tilde{n}_0 \leq p \). Then, \( \tilde{X}'_0\tilde{X}_0 \) has full rank equal to \( \tilde{n}_0 \). Augmenting \( \tilde{X}'_0\tilde{X}_0 \) by adding a column \( 1_{\tilde{n}_0} \) does not change the rank, because \( \tilde{X}'_0\tilde{X}_0 \) only has \( \tilde{n}_0 \) rows. Now, adding the row \( (1'_{\tilde{n}_0}, 0) \) increases by one the number of linearly independent rows (because if \( u \neq 0 \), \( u'1_{\tilde{n}_0} = 0 \), and \( u'\tilde{X}'_0\tilde{X}_0 = 1'_{\tilde{n}_0} \)), then \( u'\tilde{X}'_0\tilde{X}_0u = 0 \), which cannot be true because \( \tilde{X}'_0\tilde{X}_0 \) is full rank). Therefore, \( A \) is full rank and there is a unique solution for \( z \).

Now, assume \( \tilde{n}_0 = p + 1 \). Then, \( \tilde{X}'_0\tilde{X}_0 \) has rank \( p \). Assume that \( 1_{p+1} \) does not belong to the column space of \( \tilde{X}'_0 \). Then, \( 1_{p+1} \) does not belong to the column space of \( \tilde{X}'_0\tilde{X}_0 \) (because the columns of \( \tilde{X}'_0 \) and \( \tilde{X}'_0\tilde{X}_0 \) span the same space.) As a result, the rank of \( (\tilde{X}'_0\tilde{X}_0 \ 1_{p+1}) \) is \( p + 1 \). Moreover, because \( 1'_{p+1} \) does not belong to the row space of \( \tilde{X}'_0\tilde{X}_0 \), adding the row \( (1'_{p+1}, 0) \) increases the rank of \( A \) by one. In this case, again, \( A \) is full rank and there is a unique solution for \( z \).

Now, assume \( \tilde{n}_0 > p + 1 \). In this case, \( A \) is rank deficient and \( \tilde{X}'_0\tilde{X}_0 \) is rank deficient. By the same arguments as before rank\( (A) = p + 2 \). Consider the rank of the augmented matrix \( (A \ c) \)

\[
\text{rank}(A \ c) = \text{rank}\left( \begin{array}{cc} \tilde{X}'_0\tilde{X}_0 & 1_{\tilde{n}_0} \\ 1'_{\tilde{n}_0} & 0 \end{array} \tilde{X}'_0X_1 - (\lambda/2)\tilde{\Delta}_1 \right)
\]

Assume that any matrix composed by \( p + 2 \) or more rows of \( (\tilde{X}'_0 \ 1_{\tilde{n}_0} \ \tilde{\Delta}_1) \) has full column rank. Assume also that \( \lambda > 0 \). Then, there is no linear combination of the columns of \( (\tilde{X}'_0\tilde{X}_0 \ 1_{\tilde{n}_0}) \) that

29
is equal to $\tilde{X}_0^t X_1 - (\lambda/2)\tilde{\Delta}_1$. As a result,

$$\text{rank}(A c) = \text{rank}(A) + 1$$

and the system has no solution. We conclude that, under the stated assumptions, if $\lambda > 0$ then there is a unique solution $W$ with at most $p + 1$ non-zero components.

In contrast, for $\lambda = 0$ it is easy to obtain examples with multiple solutions for the case $n_0 > p + 1$, even if any matrix composed by $p + 2$ or more rows of $(\tilde{X}_0^t 1_{n_0} \Delta_1)$ has full column rank. $\square$

**Lemma A.1 (Optimality of Delaunay for the Compound Discrepancy, Rajan (1994))**

Suppose the assumptions of Theorem 1 hold and let $Z \in CH(X_0)$. Consider a solution $\tilde{W} = (\tilde{W}_{n_1+1}, \ldots, \tilde{W}_n)'$ of the problem

$$\min_{W \in [0,1]^{n_0}} \sum_{j=n_1+1}^{n} W_j \|X_j - Z\|^2,$$

subject to the constraints in A.2. Then, non-zero values of $\tilde{W}_j$ occur only among the vertices of the face of the Delaunay complex containing $Z$. $\square$

**Proof of Lemma A.1**

The proof of this lemma closely follows the proof of Lemma 10 in Rajan (1994) but does not rely on general position of the set of points. For a point $X \in \mathbb{R}^p$, consider the transformation $\phi : X \to (X, \|X\|^2)$. The images under $\phi$ of points in $\mathbb{R}^p$ belong to the paraboloid of revolution $P$ with vertical axis and equation $x_{p+1} = \sum_{i=1}^{p} x_i^2$. By Theorem 17.3.1 in Boissonnat and Yvinec (1998), the faces of the Delaunay complex of the $n_0$ points $X_{n_1+1}, \ldots, X_n$ in $\mathbb{R}^p$ are obtained by projecting the faces of the lower envelope of the convex hull of the $n_0$ points $\phi(X_{n_1+1}), \ldots, \phi(X_n)$, obtained by lifting the $X_j$'s onto the paraboloid $P$.

Now consider a point $\left(\sum_{j=n_1+1}^{n} W_j x_j, \sum_{j=n_1+1}^{n} W_j \|X_j\|^2\right)$ subject to the constraints in A.2. This point is equal to $\left(Z, \sum_{j=n_1+1}^{n} W_j \|X_j - Z\|^2 + \|Z\|^2\right)$ and belongs to the convex hull of $\phi(X_{n_1+1}), \ldots, \phi(X_n)$. Hence, a solution of A.1 for a fixed $Z$ is given by a point with the lowest $(p+1)$-th coordinate. It is a point on the lower envelope of the convex hull of $\phi(X_{n_1+1}), \ldots, \phi(X_n)$, so $Z$ belongs to a $p$-face of the Delaunay complex. As a consequence, the only non-zero entries of $\tilde{W}$ occur only among the vertices of the face of the Delaunay complex of the columns of $X_0$ containing $Z$. $\square$

**Proof of Theorem 2**

It is enough to prove that the result holds for one treated unit, so we consider the case $n_1 = 1$ and drop the treated units subscripts from the notation. Suppose that the synthetic control weights are given by the vector $W^*(\lambda) = (W^*_1(\lambda), \ldots, W^*_n(\lambda))'$, and that $W^*_j(\lambda) > 0$ for $j$ which is not a vertex of the face of the Delaunay complex $DT(X_0)$ containing $X_0 W^*(\lambda)$. Because $X_0 W^*(\lambda) \in CH(X_0)$, it follows from Lemma A.1 that we can always choose an $n_0$-vector of weights $\tilde{W} \in [0,1]^{n_0}$, such
that (i) $X_0 \tilde{W} = X_0 W^*(\lambda)$, (ii) $\sum_{j=n_1+1}^n \tilde{W}_j = 1$, (iii) $\tilde{W}_j = 0$ for any $j$ that is not a vertex of the face of the Delaunay complex containing $X_0 W^*(\lambda)$, and (iv) $\tilde{W}$ induces a lower compound discrepancy than $W^*(\lambda)$ relative to $X_0 \tilde{W} = X_0 W^*(\lambda)$,

$$\sum_{j=2}^n \tilde{W}_j \|X_j - X_0 \tilde{W}(\lambda)\|^2 < \sum_{j=2}^n W^*_j(\lambda)\|X_j - X_0 W^*(\lambda)\|^2.$$  \hspace{1cm} (A.3)

For any $W \in [0, 1]^{n_0}$ it can be easily seen that

$$\sum_{j=2}^n W_j \|X_j - X_1\|^2 = \sum_{j=2}^n W_j \|X_j - X_0 W\|^2 + \|X_1 - X_0 W\|^2.$$  \hspace{1cm} (A.4)

Combining equations (A.3) and (A.4) with the fact that $\|X_1 - X_0 \tilde{W}\|^2 = \|X_1 - X_0 W^*(\lambda)\|^2$, we obtain

$$\sum_{j=2}^n \tilde{W}_j \|X_j - X_1\|^2 < \sum_{j=2}^n W^*_j(\lambda)\|X_j - X_1\|^2.$$

As a result

$$\|X_1 - X_0 \tilde{W}\|^2 + \lambda \sum_{j=2}^n \tilde{W}_j \|X_j - X_1\|^2 < \|X_1 - X_0 W^*(\lambda)\|^2 + \lambda \sum_{j=2}^n W^*_j(\lambda)\|X_j - X_1\|^2,$$

which contradicts the premise that $W^*(\lambda)$ is a solution to (6). \hfill \Box

**Lemma A.2 (Sum of Weights)** For $j = n_1 + 1, \ldots, n$, denote $S_j(\lambda) = \sum_{i=1}^{n_1} W^*_i(\lambda)$, the sum of weights given to a particular control unit across all the synthetic units. Under Assumption 1, for any $\lambda > 0$:

1. $\sum_{j=n_1+1}^n S_j(\lambda) = n_1$ almost surely,
2. $E[S_j(\lambda)] = n_1/n_0$ for every $j = n_1 + 1, \ldots, n$,
3. $\rho[S_j(\lambda), S_k(\lambda)] = -1/(n_0-1)$ for any $j \neq k$, where $\rho[S_j(\lambda), S_k(\lambda)] = \text{Cov}[S_j(\lambda), S_k(\lambda)]/\sqrt{V[S_j(\lambda)]}$.

**Proof of Lemma A.2**

The first assertion holds because each of the $n_1$ synthetic units is created as a convex combination of control units. The second assertion is a consequence of the previous one, the linearity of the expectation operator and exchangeability. For the third assertion, notice that the first statement of the lemma implies $V[\sum_{j=n_1+1}^n S_j(\lambda)] = 0$ which in combination with exchangeability leads to:

$$n_0 V[S_{n_1+1}(\lambda)] + n_0(n_0-1)\text{Cov}[S_{n_1+1}(\lambda), S_{n_1+2}(\lambda)] = 0.$$  \hspace{1cm} (A.5)

A consequence of equation A.5 is that $\rho[S_{n_1+1}(\lambda), S_{n_1+2}(\lambda)] = \text{Cov}[S_{n_1+1}(\lambda), S_{n_1+2}(\lambda)]/V[S_{n_1+1}(\lambda)] = -1/(n_0-1).$ \hfill \Box
