ABSTRACT: We develop and estimate a joint model of the education and teacher-expectation production functions that identifies both the distribution of biases in teacher expectations and the impact of those biases on student outcomes via self-fulfilling prophecies. The identification strategy leverages insights from the measurement-error literature and a unique feature of a nationally representative dataset: two teachers provided their educational expectations for each student. We provide novel, arguably causal evidence that teacher expectations affect students' educational attainment. Estimates suggest that the elasticity of college completion with respect to teachers' expectations is about 0.12. On average, teachers are overly optimistic about students' ability to complete a four-year college degree. However, the degree of over-optimism of white teachers is significantly larger for white students than for black students. This highlights a nuance that is frequently overlooked in discussions of biased beliefs: unbiased (i.e., accurate) beliefs can be counterproductive if there are positive returns to optimism or if there are socio-demographic gaps in the degree of teachers' over-optimism, both of which we find evidence of. We use the estimated model to assess the effects of two policies on black students' college completion: hiring more black teachers and "de-biasing" white teachers so that they are similarly optimistic about black and white students.

1 Introduction

At least since Becker (1964) cast schooling as an investment in human capital, economists have sought to understand the factors that drive variation in educational outcomes. Socio-demographic gaps in educational attainment have received particular attention, since education facilitates upward economic and social mobility across generations (Bailey and Dynarski, 2011) and increased earnings (Card, 1999).¹ Attainment gaps are especially concerning if they reflect sub-optimal investments in human capital by under-represented or historically disadvantaged groups (e.g., racial minorities).

Teacher expectations constitute one potentially important, but relatively understudied, educational input that might contribute to socio-demographic gaps in educational attainment. Despite pervasive views that teacher expectations matter, however, it is difficult to credibly identify their causal effects on student outcomes (Brophy, 1983; Jussim and Harber, 2005; Ferguson, 2003). The reason is that observed correlations between teacher expectations and student outcomes could reflect accurate forecasts or a causal relationship. In the first case, expectations do not drive student outcomes, but instead reflect the same factors that drive educational attainment. In the second case, a causal impact arises if incorrect (i.e., biased) teacher expectations create self-fulfilling prophecies in which investments made in or by students are altered, thereby leading to outcomes that resemble teachers' initially incorrect beliefs (Loury, 2009; Glover et al., 2015).²

In this paper, we develop and estimate an econometric model of the teacher-expectation and education production functions. The model is designed to address the fundamental endogeneity problem arising if teacher expectations reflect omitted variables that also drive education outcomes (Gregory and Huang, 2013; Boser et al., 2014). To identify causal effects, we exploit a unique feature of a nationally-representative longitudinal dataset: two teachers provide their educational expectations for each student.³ When teachers disagree about a particular student, which they frequently do, they provide within-student, within-semester variation in expectations, which we argue below is conditionally random. We leverage this variation to identify the impact of expectations on educational attainment.

¹Among other outcomes, education also affects civic engagement (Dee, 2004a; Milligan et al., 2004), health (Grossman, 2006) and crime (Lochner and Moretti, 2004; Machin et al., 2011).

²We are not the first to examine bias and self-fulfilling prophecies in the classroom. Rist (1970) provides a rather harrowing account of how subjective teacher perceptions, driven largely by social class, affected how both teachers and students behaved in the classroom. Eventually, these behaviors produced student outcomes that corresponded to the teachers' initial and negative beliefs about students from lower social classes. Both Jussim and Eccles (1992) and Jussim and Harber (2005) recognize how accuracy and self-fulfilling prophecies could contribute to a correlation between expectations and outcomes.

³Previous research has leveraged this feature to estimate the effect of student-teacher racial match on teachers' perceptions and expectations via student-fixed effects models (Dee, 2005; Gershenson et al., 2016).

Our econometric approach borrows from the measurement error literature to model diverging teacher expectations about the same student as possible mis-measurements of an underlying true objective probability of success. Intuitively, the model uses one teacher’s expectation to control for unobserved factors that both teachers use to form expectations and which affect student educational attainment.⁴

Prior to specifying and estimating a formal model that disentangles accurate forecasts from the biased beliefs that fuel self-fulfilling prophecies, the current study begins by documenting several interesting patterns in the teacher expectations data. First, we find that teacher expectations are informative, and remain so even after conditioning on a rich set of academic, demographic, and socioeconomic controls, as well as school fixed effects and the other teacher’s expectation. Second, on average, teachers are optimistic: teachers expect more college degrees than are earned.⁵ Third, teacher expectations respond to information that would presumably affect college-going, such as family income, standardized test scores, and ninth-grade GPA. Fourth, teachers frequently disagree about how far a given student will go in school. The most common margin for disagreements is between teachers who expect “some college” and teachers who expect a four-year college degree, which, in addition to the general importance of a college degree for socio-economic success, is the reason we focus our analysis primarily on this margin.

We then further examine teacher disagreements, as they are key to the identification of causal effects. Earlier research has used the same data set to document systematic disagreements by race in teachers’ educational expectations for students (Gershenson et al., 2016). We incorporate this finding into our main analysis by allowing for a “same race” interaction in the teacher-expectation production functions. Beyond that, however, we show that teacher disagreements are not due to actual differences in which skills each teacher observes (measured for example by math versus reading test scores). Instead, we show that disagreements appear to be driven by transitory, relatively unimportant factors that are arguably excluded from the education production function. For example, we find that disagreements arise when a student behaves passively in English class but not in math class. This affects the English teacher’s expectation but not the math teacher’s expectation. This type of within-student, within-semester variation in passiveness represents transitory, arguably random departures from the student’s steady-state level of passiveness. Reduced-form analyses use observed

⁴Our identification strategy relates intuitively to the strategy in Ashenfelter and Krueger (1994), who study identical twins with diverging schooling levels to mitigate bias due to omitted variables bias (e.g., ability) in estimating returns to schooling. See Bound and Solon (1999) for further discussion of the use of twins to address endogeneity problems in labor and education economics.

⁵This does not necessarily imply that teachers are on average wrong at the time that expectations information was collected. It is possible that unexpected aggregate shocks occurring after expectations data were collected shifted behavior (Van der Klaauw and Wolpin, 2008).

differences in teachers’ assessments of students’ passiveness, as well as of other character traits, to instrument for teachers’ educational expectations for students. The resulting instrumental variable (IV) estimates provide preliminary evidence that teacher expectations have a causal impact on educational attainment.

Motivated by these reduced-form results, we apply lessons from the measurement-error literature to develop an econometric model that jointly estimates teacher expectations and student outcomes. The measurement error model formalizes the common factors that drive teacher expectations *and* directly enter the education production function as an unobserved or “latent” factor. The latent factor determines the objective probability, absent bias, that students complete a college degree. It is identified off of two teacher expectations along with the observed student outcome. Each teacher’s expectation is thus treated as a possible mis-measurement of the objective probability, which is determined by the latent factor.⁶ Providing an economic interpretation of a latent factor using lessons from the measurement error literature is similar to Heckman et al. (2006), who develop a model where latent factors capture both cognitive and non-cognitive skills. An innovation in our approach is that we also provide an explicit economic interpretation of the measurement error (error terms in teacher expectations equations) that lead to disagreements between teachers. Specifically, we interpret those errors as biases in teachers’ expectations, which we then allow to be inputs in the education production function that potentially create self-fulfilling prophecies.

Estimates of both the IV and measurement-error models provide compelling evidence of a causal impact of teachers’ expectations on the likelihood of college completion. The estimates suggest that the elasticity of the likelihood of college completion with respect to teachers’ expectations is about 0.12. In an earlier contribution, Rosenthal and Jacobson (1968) report effects of informing teachers that some randomly selected students are high-aptitude. These students eventually perform better on tests, which provides some basis for the view that teacher expectations matter in the sense that randomly assigned biases can become self-fulfilling prophecies. Our findings using a longitudinal data set show that these so-called “Pygmalion Effects” can have long-run impacts on educational attainment.

Having shown that teacher expectations matter, we use model estimates to study how teacher expectations can put black students at a disadvantage. This is motivated by previous research using the same data set showing that white teachers’ expectations are systematically lower than are black teachers’ expectations when both are evaluating the same black student (Gershenson et al., 2016). Systematic disagreements suggest that if expectations do matter for student outcomes through self-fulfilling prophecies, they could contribute to attainment

⁶The use of multiple measures to recover the distribution of latent factors goes back to the psychometric literature (Jöreskog and Goldberger, 1972).

gaps between black and white students. The model reveals that this is indeed the case. Recall, our model allows us to identify objective probabilities of college completion and to compare these to teacher expectations. Doing so suggests that teachers are on average optimistic: their expectations are higher than the student’s objective probability of college completion. However, white teachers are systematically less optimistic about black students. An overlooked nuance is therefore that white teachers are more accurate about black students in that their expectations are closer to the objective probability. However, since higher expectations lead to better outcomes, “accuracy” in this context amounts to a selective lack of optimism that puts black students at a disadvantage.⁷

Finally, we use our estimated model to explore two policies that could attenuate the attainment gap between black and white students. The first policy is to hire more black teachers (Putman et al., 2016). This would increase the probability that black students face a black teacher, which according to our estimated model would increase the likelihood that a black student faces higher expectations. The second is to de-bias white teachers. A number of interventions have shown promise in reducing racially-based unconscious bias (Devine et al., 2012), including some in the education context (Carnes et al., 2015; Okonofua et al., 2016).⁸ We operationalize this counterfactual by simulating white teachers who, regardless of student race, form the same expectations for a given objective probability of college completion. Results show that these policies can help some black students, especially those who are above the median objective probability of college completion upon entering the 10th grade.

Our study contributes to research examining how teachers affect student outcomes. A number of studies have shown that teachers are important inputs in the education production function (Chetty et al., 2013; Hanushek and Rivkin, 2010). Other studies have recognized that same-race teachers are more effective, especially for racial minorities and women (Carrell et al., 2010; Dee, 2004b). However, it remains unclear what specific behaviors and characteristics make teachers effective. Our study suggests one possible mechanism: teachers’ expectations that potentially affect student outcomes. Teachers might directly impart biased expectations to students or do so indirectly by modifying how they teach stigmatized students (Burgess and Greaves, 2013; Ferguson, 2003; Mechtenberg, 2009). In either case, biased expectations function like a self-fulfilling prophecy that perpetuates educational

⁷These findings are consistent with literature that has established robust evidence that on average, non-white students perform better and are more engaged when paired with same-race teachers (Dee, 2004b; Fairlie et al., 2014).

⁸Additionally, Dobbie and Fryer Jr. (2015) provide suggestive evidence that some pre-service teacher training programs can reduce teachers’ racial biases and increase their educational expectations for children from disadvantaged backgrounds.

attainment gaps.⁹ These effects might be particularly salient for relatively disadvantaged students who rarely interact with college-educated adults outside of school settings (Jussim and Harber, 2005; Lareau, 2011; Lareau and Weininger, 2008), since a model of costly information acquisition would predict that such students rely on teacher expectations as a primary source of information.

We also contribute to economic literature on biased information sources and self-fulfilling prophecies. Several studies examine biases in beliefs and human capital investments (Cunha et al., 2013; Wiswall and Zafar, 2015). Regarding teacher biases, Lavy and Sand (2015) identify primary school teachers in Israel who have “pro-boy” grading bias by comparing students’ scores on “blind” and “non-blind” exams.¹⁰ Our paper shows evidence that such biases could have long-run effects on college completion. Similarly, Glover et al. (2015) study managers’ perceptions of cashiers and examine how negative perceptions (implicit biases) against certain demographic groups can lead to lower performance.¹¹ A key difference in our study is that, instead of negative perceptions, we observe actual expectations over an economic outcome along with realized outcomes. Thus, we are able to explicitly define bias as a deviation of expectations from objective probabilities and then to identify the impact of such bias on outcomes through self-fulfilling prophecies.

More broadly, our paper contributes to research on the importance of subjective expectations. The idea that subjective beliefs (rather than objective probabilities) drive individual behavior is not new (Savage, 1954; Manski, 1993). However, despite mounting evidence that subjective expectations can affect important economic outcomes, they are only recently entering into economic analyses of decision-making (Manski, 2004; Hurd, 2009).¹² One reason is that data on subjective expectations have rarely been collected. Another reason is that it is difficult to assess whether beliefs have causal effects on outcomes absent experimentally-induced exogenous variation. Our approach addresses this issue by using lessons from the measurement error literature and leveraging multiple reported subjective expectations about a single objective probability. We therefore offer a methodology for using observational data

⁹Fortin et al. (2015) and Jacob and Wilder (2010) examine how students’ expectations evolve over time and might explain demographic gaps in achievement.

¹⁰Terrier (2015) finds similar effects of gender-based grading bias on short-run achievement and subsequent course-taking in France.

¹¹Similarly, Loury (2009) develops an informal model where taxi drivers incorrectly believe that black passengers are more likely than white passengers to rob them. This belief leads drivers to avoid black passengers. In response, black passengers with no criminal intent find other forms of transportation. This affects the composition of black passengers waiting for a cab so that in equilibrium the original biases become true.

¹²Contributions to this line of work include the studies cited above along with numerous papers linking beliefs to economic behaviors such as voting (Chiang and Knight, 2011; DellaVigna and Kaplan, 2007; Gentzkow and Shapiro, 2006), risky sexual behavior (Delavande and Kohler, 2016), and financial decisions (Hudomiet et al., 2011).

to assess how beliefs affect behavior, which could be extended to other contexts.

Section 2 describes the data set used in the project and documents some basic facts about the information contained in teacher expectations and how and why teachers disagree. Section 3 develops the main econometric model and describes identification and estimation. Sections 4 and 5 present the main results and policy simulations, respectively. Section 6 concludes.

2 Data Set and Preliminary Data Analysis

In this section, we discuss the data set used in the project and conduct a preliminary data analysis of teacher expectations and student educational attainment. Section 2.1 introduces the 2002 Education Longitudinal Study (ELS 2002). Section 2.2 establishes that teacher expectations are informative, i.e., that they are strongly predictive of student outcomes. This empirical pattern could reflect that teacher expectations are accurate forecasts of student outcomes or alternatively that they influence student outcomes through self-fulfilling prophecies. To examine these alternatives further, Section 2.3 studies how teacher expectations are produced. We pay particular attention to understanding why two teachers disagree (in terms of reported expectations) about the same student. In Section 2.4, we provide preliminary evidence that we can exploit teacher disagreements to estimate causal effects.

2.1 ELS 2002

The ELS 2002 is a nationally representative survey of the cohort of U.S. students who entered 10th grade in 2002.¹³ The ELS data contain rich information on students' socio-demographic backgrounds as well as secondary and postsecondary schooling outcomes (including educational attainment through 2012, or within 8 years of an "on time" high school graduation). Students were sampled within schools and school identifiers facilitate within-school (school fixed effects) analyses. The data also contain a number of observed school and teacher characteristics, including teachers' experience, demographic background, credentials, and expectations and perceptions of specific students.

The main analytic sample is restricted to the 6,060 students for whom the above-mentioned variables are observed.¹⁴ Because there are two teacher expectations per student, the analytic

¹³The ELS data are collected, maintained, and made available to researchers by the National Center for Education Statistics. See <https://nces.ed.gov/surveys/els2002>.

¹⁴All sample sizes are rounded to nearest ten in accordance with NCES regulations for restricted data. The instrumental variables analysis described below uses a further restricted sample, for whom a wider range

sample contains 12,130 teachers. Table 1 summarizes the students who compose the analytic sample. Column (1) does so for the full sample and columns (2)-(5) do so separately by student race and sex. The outcome of interest, students' educational attainment, is summarized in three ways: percentage of students who earn a four-year college degree (or more), percentage of students who fail to complete high school, and average years of schooling. About 45% of students in the sample completed a four-year degree, though whites and females were significantly more likely to do so than blacks and males, respectively. This is consistent with demographic gaps in educational attainment observed in other datasets (Bailey and Dynarski, 2011; Bound and Turner, 2011; Cameron and Heckman, 2001). The racial gaps in educational attainment are particularly stark, as whites were about 20 percentage points (50%) more likely to graduate from college than blacks while blacks were twice as likely as whites to fail to complete high school. Racial differences in educational attainment are also apparent in Figure 1, which provides a histogram for educational attainment categories for the full sample and then separately for blacks, whites, males, and females.

The key teacher-expectation variable we use is based on teachers' responses to the following question: "*How far do you think [STUDENT] will go in school?*" Teachers answered this question by selecting one of seven mutually exclusive categories.¹⁵ In most of our subsequent analysis, we exploit a unique feature of the ELS 2002's design: two teachers, one math and one English Language Arts (ELA), provided their subjective expectations and perceptions of each student. Teachers' expectations are summarized in the next section of Table 1. Overall, about 64% of teachers expected the student to complete a four-year college degree. This suggests that teachers, on average, are too optimistic about students' college success, since only 45% of students complete a four-year degree. This over-optimism is apparent in each demographic group, though teachers' expectations for black students are significantly lower than for white students, as are expectations for male students relative to females. This points to an interesting feature in the data that foreshadows our results: teacher expectations for black students are not necessarily low relative to observed outcomes. Rather, they are less inflated relative observed outcomes in comparison to expectations for white students. Still, observed racial and sex gaps in expectations are consistent with the patterns in actual educational attainment described above, suggesting that teachers' expectations are informative. However, while math and ELA teachers' expectations are similar on average, ELA teachers' expectations tend to be slightly higher, particularly among black students. This shows that teachers occasionally disagree about how far a particular student will go

of teacher-perception variables are observed.

¹⁵Options were Less than high school graduation; High school graduation or GED only; Attend or complete 2-year college/school; Attend college, 4-year degree incomplete; Graduate from college; Obtain Master's degree or equivalent; Obtain PhD, MD, other advanced degree.

in school. Below, we further investigate the sources of teacher disagreements and consider how such disagreements can be leveraged to identify the impact of expectations on student outcomes.

The final two panels of Table 1 summarize students' academic and socioeconomic characteristics. A comparison of columns (2) and (3) shows that white students have significantly higher test scores, GPAs, and household incomes than black students, as well as better educated mothers, all of which is consistent with longstanding racial disparities in academic performance and socioeconomic status (Fryer, 2010). Another notable difference by student race is in their assigned teacher's race: black students are four to five times as likely as white students to be assigned a black teacher, which is due to non-white teachers being more likely to teach in majority non-white schools (Hanushek et al., 2004; Jackson, 2009). Nonetheless, the majority of students, white and black, have white teachers. Columns (4) and (5) of Table 1 show that girls have higher GPAs and perform better on reading assessments than boys, while boys perform better on math assessments. This is again consistent with the extant literature (Jacob, 2002). Unsurprisingly, there are no significant differences in SES by sex, since boys and girls live in the same neighborhoods and attend the same schools.

Table 2 similarly summarizes the teachers represented in the analytic sample. Overall, 11% of teachers are nonwhite and nonwhite teachers are evenly represented across subjects and sex. The average teacher has about 15 years of experience though 16% of teachers have ≤ 3 years of teaching experience. Math teachers are more experienced than English teachers, on average, as are black teachers relative to white teachers. Almost half of teachers have an undergraduate degree in the subject they teach. A similar percentage hold a graduate degree. The bottom panel of Table 2 confirms that black teachers are significantly more likely to teach black students than are teachers from other racial backgrounds.

2.2 Teacher Expectations are Predictive

Are teacher expectations informative? This section demonstrates that teacher expectations about educational attainment are predictive and, moreover, that they remain so even after controlling for a number of factors that jointly determine teacher forecasts and student outcomes. In this section, and for most of the remainder of our study examining teacher expectations and student outcomes, we focus on the college-completion margin since recent research explicitly notes that individuals with some college, but less than a four-year degree, have socioeconomic trajectories that closely resemble those of high school graduates (Lundberg et al., 2016). This choice is also due to the striking patterns observed in Figure 1: blacks are significantly more likely than whites to only complete "some college." This suggests that

college completion, relative to college entrance, is an important margin to consider in the analysis of racial attainment gaps. Thus, we define students’ educational attainment and teachers’ educational expectations for the student in the same way: the student outcome of interest in the primary analyses is an indicator for “student completed a four-year college degree or more” (as of 2012, 8 years removed from an on-time high-school graduation) and the independent variable of interest is an indicator for “teacher expects a four-year college degree or more.”

Figure 2 plots the percentage of students who complete a four-year college degree for each category of teacher expectations, separately for math and ELA teachers. According to the figure, higher expectations are associated with a higher probability of college completion. Interestingly, however, teacher forecasts are subject to error. For example, of students for whom ELA teachers expect some college (but not college completion), roughly 15% go on to obtain a 4-year degree. Forecast errors tend to be in the opposite direction, however. Fewer than 60% of students whose math or ELA teachers expect a 4-year degree actually obtain one. This pattern extends to students for whom teachers expect a Masters or other higher degree, who obtain at least a 4-year degree roughly 80% and 85% of the time, respectively. In other words, though teacher expectations are predictive of student outcomes, on average teachers seem to over-estimate educational attainment, which is consistent with patterns found in Table 1.

One reason teacher expectations predict student outcomes is that teachers use information they have on students, such as student performance in class or socioeconomic background, to generate accurate forecasts. Therefore, we would expect expectations to become less predictive of outcomes once we control for factors that potentially affect both. Table 3 presents OLS estimates of linear regressions of the form

$$y_i = \gamma_E T_{Ei} + \gamma_M T_{Mi} + X_i \beta + \epsilon_i, \tag{1}$$

where the T ’s denote teacher expectations, y denotes student outcomes, and i indexes students.¹⁶ Either γ_E or γ_M can be restricted to equal zero, where E and M index ELA and math teachers, respectively. The vector X includes a progressively richer set of statistical controls, up to and including school fixed effects (FE). Standard errors are clustered by school, as teachers and students are nested in schools (Angrist and Pischke, 2008).

¹⁶To allay concerns that these results are driven by students with extreme levels of attainment, Table S1 in Appendix A reports OLS estimates of equation (1) for the restricted sample that excludes students who either did not complete high school or who earned a graduate degree. We present OLS estimates of these linear probability models (LPM) for ease of interpretation and to facilitate the inclusion of school fixed effects. However, estimates of the probit analog to equation (1) yield qualitatively similar patterns. Probit estimates are reported in Table S2 in Appendix A.

Columns (1) and (2) of Table 3 report simple bivariate regressions of y on the ELA and math teachers' expectations, respectively. The point estimates are nearly identical, positive, and strongly statistically significant. Of course, these positive correlations cannot be given causal interpretations since there are many omitted factors that jointly predict student outcomes and teachers' expectations (e.g., household income). In subsequent columns of Table 3 we attempt to reduce this omitted-variables bias by explicitly controlling for such factors. In column (3), we simultaneously condition on both teachers' expectations. Interestingly, though both estimates of γ decrease in magnitude, they remain nearly identical to one another and both remain individually statistically significant. That both teachers' expectations remain individually significant indicates that there is substantial within-student variation in teacher expectations (i.e., teachers frequently disagree). Intuitively, one teacher's expectation can be viewed as a proxy for many of the other factors that influence y ; indeed, this idea foreshadows the formal identification strategy introduced in Section 3.

Subsequent columns of Table 3 continue to add covariates to the model, which lead to a similar pattern in the estimated γ : the estimated effects of expectations decrease in magnitude, but remain positive, similar in size to one another, and individually statistically significant. The richest (and our preferred) specification, which conditions on students' socio-demographic background, past academic performance, and school FE, is reported in column (7). These estimates suggest that conditional on the other teacher's expectation and a rich set of observed student characteristics including sex, race, household income, mother's educational attainment, 9th grade GPA, and performance on math and ELA standardized tests, the average marginal effect of changing a teacher's expectation that a student will complete college from zero to one increases the student's likelihood of earning a college degree by about 15 percentage points. Columns (8) and (9) show that the point estimates are similar in magnitude for white and black students, though the black-sample estimates are less precisely estimated, likely due to the significantly smaller sample size.

At first blush, 0.15 might seem like an implausibly large effect, since 45% of students in the sample earned a four-year degree. But it is unlikely that the policy-relevant counterfactual is changing a teacher's expectation of the probability that a student earns a college degree from zero to one. Instead, consider the average marginal effect of more modest 10- or 20- percentage point increases in the probability that a teacher places on a student completing college, which corresponds with the unconditional black-white gap in expectations shown in Table 1. The effects of these changes are about 1.5 and 3.0 percentage points, respectively. From the base college-completion rate of 45%, these represent modest, but nontrivial, increases of 3.3 to 6.7%. These effect sizes are remarkably similar to those found in other evaluations of primary-school inputs' impacts on post-secondary outcomes. For example, Dynarski et al.

(2013) find that assignment to small classes in primary-school increased the probability that students earned a college degree by 1.6 percentage points. Similarly, Chetty et al. (2013) find that a one-SD increase in teacher effectiveness increases the probability that a student attends at least four years of college between the ages of 18 and 22 by about 3.2%.¹⁷ Still, even with these rich controls and conditioning on the other teacher’s expectation, the threat of omitted-variables bias remains. We discuss alternatives to OLS estimation of equation (1) that address this concern below.

2.3 The Teacher Expectations Production Function

To understand whether teacher expectations have a causal impact on student outcomes, we must first understand what drives variation in teacher expectations. While a large literature in education and psychology has discussed the potential importance of teacher expectations, less thought has been given to the formation of teacher expectations. Thus one contribution of the current study is a systematic analysis of the teacher expectation production function. A key point here is that teachers frequently disagree about a particular student’s educational prospects, a fact which we leverage in our identification of the impact of teacher expectations on student outcomes. Indeed, the transition matrices reported in Table 4 document the frequency of such disagreements. The majority of disagreements are over whether or not students who enter college will earn a 4-year college degree, rather than more substantial disagreements.

This suggests that disagreements are often subtle, and might hinge on transitory or relatively unimportant factors. For example, chance encounters between a teacher and a student in the hallway might affect the teacher’s expectations for that student, even though the behavior was unrepresentative of the student and will not affect college-going. Such factors are normally unobserved by the econometrician. However, the ELS includes a battery of teacher-specific perceptions of each student that might affect one teacher’s expectation, but not another’s.¹⁸ Specifically, teachers were asked whether each student was “passive” and “attentive” in class. Similarly, students were asked whether they found math and reading to be “fun.” While students’ steady-state levels of passiveness, attentiveness, and enjoyment of learning are non-cognitive skills that likely affect educational attainment (Cunha et al., 2010), subtle differences in the expression of these traits between 10th-grade math and English classrooms should not influence students’ educational attainment. Of course, high-school students may behave differently in different classrooms for myriad reasons, including

¹⁷Chetty et al. (2013) do not observe actual college completion and instead use this as a proxy.

¹⁸These variables are summarized in Table S3 in Appendix A and are missing for < 5% of students.

but not limited to the peer-composition of the classroom and the time of day the class meets (Carrell and Hoekstra, 2010; Figlio, 2007; Imberman et al., 2012; Shapiro et al., 2015). Such differences might well affect teachers’ expectations, however, since English teachers do not typically observe students’ behavior in math classrooms, and vice versa.

In particular, the aim is to assess whether differences in teachers’ reports of “passiveness” or “attentiveness” about the same student predict differences in teachers’ expectations even after we have conditioned on the full set of observable characteristics used in the final specification of equation (1). To assess this possibility, we estimate linear teacher expectation production functions of the form

$$T_{ij} = X_i\beta_j + Z_{iM}\pi_{jM} + Z_{iE}\pi_{jE} + \nu_{ij}, j \in \{M, E\} \quad (2)$$

where X_i are the student characteristics included in equation (1) that jointly affect teacher expectations and student outcomes. In contrast, Z_j are vectors of possibly transitory, subject- and teacher-specific factors that are unique to each student-teacher dyad.

Columns (1) and (2) of Table 5 report estimates of equation (2) for the full analytic sample. For context, regressing ELA and math teachers’ expectations on X alone yields an R^2 of about 0.5, meaning that this set of fairly standard measures of socio-demographic background, achievement, and school quality explains about half the variation in teacher expectations. However, it is immediately apparent that the classroom-specific variables (Z) are informative: adding them increases the adjusted- R^2 by 0.05 (11%) and they are strongly jointly significant. Moreover, they tend to be individually significant, and intuitively signed. For example, column (1) shows that being perceived as passive in English class significantly reduces the likelihood that the English teacher expects a college degree, but has no effect on the math teacher’s expectation. The reverse is true for being perceived as passive in math class (column (2)).

These findings are fascinating, as they imply that teachers are not responding to the student’s steady-state (underlying) demeanor, but rather that teachers are forming expectations based on within-semester, within-student, between-class variation in students’ passiveness. Similar differences are observed in teachers’ perceptions of students’ “attentiveness.” Most remarkable are English teachers’ *negative* responses to whether students “find math fun.” Moreover, the Z_j are arguably excluded from equation (1), because they should not directly affect college completion. Equation (2) therefore represents a potentially valid first-stage for 2SLS estimation of equation (1). For Z_j to serve as valid instruments for teacher expectations, they must significantly predict teacher expectations after conditioning on the important drivers of educational attainment contained in X_i ; we see in Table 5 that this is

the case.

2.4 Preliminary Evidence of Causal Effects

Thus far, we have demonstrated the predictive power of teacher expectations and described their formation. We have also shown that teachers may disagree about students due to transitory shocks that are arguably excluded from the education production function. In this section, we conclude our reduced-form analysis by using these transitory shocks to instrument for teacher expectations in 2SLS estimates of the education production function specified in equation (1). In doing so, we provide preliminary evidence of a causal relationship between teacher expectations and student outcomes.

The estimates of the teacher-expectation production functions reported in columns (1) and (2) of Table 5 highlight some of the transitory shocks that likely affect expectations but not student outcomes (except through their effects on teachers' expectations). Because the transitory, between-classroom variation in students' demeanor affects teachers' expectations but arguably does not affect students' educational attainment, these variables are potential instruments for the endogenous teacher expectations in equation (1). Indeed, the teacher-expectation production functions in columns (1) and (2) can be interpreted as first-stage regressions. The instruments are strong, as evidenced by the first-stage F statistics of 16 and 20 (Stock and Yogo, 2002). The rank condition is likely satisfied as well, since the "passive in English" indicator affects the English teacher's expectation, but not that of the math teacher, and vice versa for the "passive in math" indicator.

Conditioning on the full set of teacher and student demographic variables included in X_i in equation (1), the resulting 2SLS estimates of the impact of teacher expectations on college-going are positive and statistically significant. They are also similar in magnitude to the corresponding OLS estimates, both of which are reported in the top panel of Table 5.¹⁹ Furthermore, the IV estimates are quite robust to model specification. For example, Columns (1) and (2) of Table S4 in Appendix A show that adding the means of each teacher's expectations for other (i.e., non- i) students as additional instruments for the expectations for student i , an IV strategy similar in spirit to that used in Kling (2006), yields similar point estimates and passes the over-identification test. Moreover, columns (3) and (4) show that the IV estimates are robust to controlling for teacher fixed effects in place of school fixed effects.²⁰

¹⁹Indeed, control-function Hausman Tests find no significant differences between the OLS and 2SLS estimates for the full, white, or black samples in Table 5. The estimates for the black sample are particularly imprecise, again due to the small sample.

²⁰Teacher-FE models are not the preferred specification, and thus relegated to an appendix, because the

In the following section, we develop an econometric model to assess the causal effect of teacher expectations on student outcomes. The econometric model relies on a similar identification strategy to the instrumental-variables procedure employed here: teachers might disagree about a given student due to factors that do not influence student outcomes directly (e.g., a chance positive encounter after class) but could do so indirectly by leaving a teacher with an unduly favorable perception of the student’s prospects. Our aim in this section was to find such factors in the data. A key weakness of this approach, however, is that the majority of these types of factors, by virtue of being subtle and transitory, are unlikely to be measured and are thus unobserved by the econometrician. Another limitation is that the IV procedure provides no information about the distribution of biases in teacher expectations or how expectations relate to students’ objective probabilities of completing college. This leads us to develop an econometric model using lessons from the measurement error literature (Hu and Schennach, 2008) to estimate a distribution of forecast error that not only leads teachers to disagree, but can also affect student outcomes through the mechanism of self-fulfilling prophecies.

3 A Model of Expectations and Outcomes

We develop an econometric model to isolate the causal impact of teacher expectations on college completion. The key identification challenge is that the observed correlation between teacher expectations and students’ educational attainment can reflect a causal impact (via self-fulfilling prophecies), but might also reflect that teacher expectations are accurate forecasts of student outcomes. The model disentangles these two sources of correlation. To allow teacher expectations to be accurate forecasts, we model them as functions of the same latent factor that produces student outcomes. This latent variable captures factors that produce student outcomes and that teachers use to form expectations. However, we also allow teacher expectations to incorporate forecast error, which is identified off of teacher disagreements regarding the same student. These forecast errors, in turn, are permitted to influence student outcomes, which captures the idea of self-fulfilling prophecies.

As discussed earlier, the model also allows for differences by student race in the educa-

ELS:2002 does not provide actual teacher identifiers. To facilitate such analyses, we create teacher identifiers using a probabilistic matching process, which is necessarily prone to measurement error. This procedure makes within-school matches based on teachers’ race, sex, subject, educational attainment, experience, and college majors and minors. The algorithm is likely to perform well given the relatively large number of observable teacher characteristics and the fact that the sample is limited to teachers of tenth graders; still, the possibility remains that teachers with identical observable profiles are incorrectly coded as being the same teacher. A second limitation of this approach is that it further reduces the sample, as it restricts the sample to students for whom both teachers taught multiple students.

tion production function parameters along with differences by student and teacher race in the production of teacher expectations. This allows racial mismatch between teachers and students to affect whether and to what degree teachers are biased. This feature of the model is motivated by earlier research using the same data set showing that black and white teachers, when evaluating the same black student, have different expectations about the student’s educational attainment (Gershenson et al., 2016).

The key identifying assumption is that teacher forecast error arises from factors that do not directly affect the objective probability of college completion, but might do so indirectly through their impact on teacher beliefs. This is similar to the exclusion restriction for the IV estimates discussed in section 2.3. However, by their nature, many such factors (e.g., chance positive or negative encounters with a student) are unlikely to be recorded in the data set. The framework we develop here draws upon lessons from the measurement error literature to capture these unobserved factors by estimating a distribution of teacher forecast errors, which can jointly affect teachers’ expectations and student outcomes.²¹ Section 3.1 introduces the baseline model. Section 3.2 discusses identification. Section 3.3 describes estimation.

3.1 The Econometric Model

College completion is a binary variable denoted y_i , which takes the value 1 if student i graduates from a 4-year college and 0 otherwise. The probability that $y_i = 1$ is given by:

$$Pr(y_i = 1) = \Phi(c + \theta_i + G_i\beta + b_{Ei}\gamma_E + b_{Mi}\gamma_M), \quad (3)$$

where Φ is the standard normal cdf. According to equation (3), college completion is a function of a constant c and a latent factor θ_i , where we assume that

$$\theta_i \sim N(0, \sigma_\theta^2). \quad (4)$$

²¹The techniques used in this literature draw upon the psychometric literature (see e.g., Goldberger (1972) and Jöreskog and Goldberger (1975)), where an aim is to separate measurement error from an underlying latent factor (e.g., depression) captured imperfectly by a set of measurements. These methods were later incorporated into economics where the latent factor is assigned an economic meaning. A key example is Cunha et al. (2010) who use multiple test scores to identify a latent factor capturing cognition along with measures to identify a non-cognitive skill factor. Both factors are then used in a model of human capital accumulation and labor market outcomes. Hu and Schennach (2008) extend this literature by generating conditions under which parametric assumptions can be relaxed and identification still achieved. We rely on arguments in Cunha et al. (2010) and Hu and Schennach (2008) when we discuss identification.

Together, c , θ_i , and 9th-grade GPA (G) determine the objective probability that student i , absent teacher bias (b), will attain a four-year college degree, where G is included because of evidence, explained below when we discuss identification, that lower 9th-grade GPA predicts a higher likelihood of teacher disagreements. Similar to Cunha et al. (2010), we assign an economic interpretation to θ_i . However, it is neither a student fixed effect nor a measure of student ability. Rather, it is a latent variable that captures heterogeneity in the objective probability that a student observed in the 10th grade will eventually graduate college. It is the same latent variable that will be used in the production function of teacher expectations to capture how teachers observe many of the factors that determine this objective probability.

As mentioned, the model will be separately estimated for black and white students, though we suppress race subscripts to avoid additional notation. This means that blacks and whites may exhibit different distributions of completing a college degree, which would be captured by race-specific differences in c (mean) and σ_θ . Given our interpretation of θ , these differences are not purely ability differences, but also reflect variation in the inputs received by students that could affect long-run educational outcomes, such as early childhood investments and school quality. Teacher biases, expressions for which are derived below, are given by b_{ji} , where $j \in \{E, M\}$ indexes the teacher and the γ parameters map biases to outcomes. Including biases in teachers' expectations in the education production function is an innovation of the current study that formally allows for self-fulfilling prophecies.

The econometric model jointly estimates teacher-expectation and student-outcome equations as functions of θ_i and G_i . Teacher expectations, denoted T_{ji} for teachers $j \in \{E, M\}$, are given by:

$$Pr(T_{ji} = 1) = \Phi(c_j + \phi_j\theta_i + G_i\beta_j + D_{ji} \times [c_{j,D} + \phi_{j,D}\theta_i + G_i\beta_{j,D}]). \quad (5)$$

The indicator D_{ji} takes the value of one if student i faces an other-race subject- j teacher, and zero otherwise. This captures how teacher-student racial mismatch can change how teachers form expectations for a given student with a singular objective probability of college completion (Gershenson et al., 2016). In other words, racial mismatch between teachers and students can affect whether and to what degree teachers are biased.

We define bias by combining equations (3) and (5):

$$b_{ji} \equiv T_{ji} - \Phi(c + \theta_i + G_i\beta) \quad (6)$$

so that bias is simply the difference between what a teacher reports (T_{ij}) and the objective probability that the student would complete a college degree given θ_i and G_i . This definition

of bias implies that b_{ji} is continuous, increases 1:1 with T_{ji} , and is $\in (-1, 1)$.²²

According to equation (6), teacher bias arises when a teacher’s expectations diverge from information that is common to both of them, including ninth-grade GPA and the latent factor θ_i . The model captures several potential sources of bias in teacher expectations. Based on the patterns observed in section 2.1, we allow teachers to be wrong on average, meaning c_j and $c_{j,D}$ can deviate from c . Teachers may also be wrong about how θ_i maps into outcomes, which occurs if $\phi_j \neq 1$. For example, the reduced form finding that teachers seem to over-estimate low and high educational attainment outcomes despite our controlling for a host of observables could mean that $\phi_j > 1$.²³ Teachers may also be biased in how they map observable grades G_i to outcomes, in which case $\beta_j \neq \beta$. Finally, teachers may be wrong for idiosyncratic reasons, which is captured by the standard-normal disturbances that lead to the probit functional form in equation (5).²⁴

3.2 Identification of the Econometric Model

There are two points to discuss regarding identification of the econometric model defined by equations (3)-(6). The first is whether the estimated γ are accurately interpreted as causal. Analogous to what is required for identification of the reduced form models estimated in Section 2.2, the argument is that teacher bias is exogenous in the production function of student outcomes. The second is that we need sufficient data to estimate the distribution of the latent factor, which is not a trivial condition. We discuss each in point in turn.

3.2.1 Exogeneity of Teacher Bias

For the γ_j to be given causal interpretations in equation (3), the biases (denoted b) must be exogenous, conditional on θ , c , and G . The b , in turn, are the factors that drive teacher expectations to diverge for the same student. Intuitively, this means that information that

²²In Appendix B, we estimate two alternative models. The first model uses an alternative definition of bias. The second model permits correlation in bias for two teachers evaluating the same student.

²³The term ϕ_j may capture how teachers have biased beliefs about how a given θ_i affects outcomes. It may also capture that teachers correctly map ability to outcomes, but mis-estimate θ_i . We cannot separately identify these effects. Similarly, the term β_j may represent that teachers are biased in the mapping or in their observation of G_i . Again, we are unable to separately identify these mechanisms. For ease of interpretation, we will assume that teachers observe G_i and θ_i , but incorrectly map these to outcomes when forming expectations.

²⁴In the model we estimate, we assume probit errors are independent across teachers. In Section 3.2, we introduce additional data to identify the econometric model. Using additional data, it becomes possible to relax this independence assumption. Results from a model where we do this are available from the authors and indicate that although there is some positive correlation between teacher biases, accounting for it does not affect other results.

teachers use to form expectations, but which is not used in both teachers' expectations, does not directly affect college-going. Information about student i that is commonly used by both teachers to form expectations is captured in θ_i , c , and ninth-grade GPA.

A threat to identification, then, is that differences in teacher expectations are due to factors that are not observed by both teachers, but do matter for college going. For example, consider a student who is exceptionally strong in math, but mediocre in English. A math teacher may recognize this skill when the English teacher does not. This would lead to variation in teacher expectations that is based upon differences in teacher observations of skills that might matter for college. However, the data suggest that this is not true: Figure 3 shows that the expectation gradients with respect to test scores for both teachers (ELA and math) are nearly identical for both ELA and math tests, even though these tests were not administered by teachers and the teachers did not see the students' scores. If teacher disagreements were explained by skills differences, we would expect math teachers to respond to reading test scores less strongly than would ELA teachers, and vice versa.

We formally test whether differences in students' subject-specific skills predict teacher disagreements by estimating linear probability models of the form

$$1\{T_{Ei} \neq T_{Mi}\} = \delta_1|S_{Ei} - S_{Mi}| + \delta_2G_i + X_i\delta_3 + e_i, \quad (7)$$

where S_j are subject- j test scores, $1\{\cdot\}$ is the indicator function, G is 9th-grade GPA, and X is the vector of socio-demographic controls and school fixed effects from equation (1). Estimates of δ_1 and δ_2 are reported in the top rows of Table 6. Row 1, which restricts δ_1 to equal zero, shows that disagreements are decreasing in 9th-grade GPA. This is intuitive, since there is more ambiguity regarding the future outcomes of moderate and low-performing ninth graders. Importantly, this is why we explicitly allow for G to enter in both the education and teacher expectation production functions. Thus, it is not a threat to identification. However, rows 2 and 3 of Table 6 show that subject-specific skill differences, whether included in levels or a quadratic, do not significantly predict teacher disagreements. This is consistent with the nearly overlapping plots in Figure 3 and reinforces the idea that teacher disagreements are not driven by actual differences in students' subject-specific aptitudes, which might directly enter the education production function.

Another possibility is that variation in expectations is due to large shocks that might eventually affect college completion, but that only one teacher observes. For example, one teacher may learn that a student has a learning disability and revise her expectations accordingly.²⁵ If this information is not known by the other teacher, then it is not in θ_i , which

²⁵The character Pastor Tim in the popular television show *The Americans* provides an extreme, yet

means it would be captured in b , which would undermine the exogeneity of the biases in equation (3). Of course, if both teachers are aware of the learning disability, then that information is captured by θ_i and is therefore controlled for in equation (3), which means that, conditional on θ_i , the γ are identified. To assess whether large shocks or pieces of information are known to only one teacher and accordingly drive differences in teacher expectations, we estimate variants of equation (7) that replace $|S_{Ei} - S_{Mi}|$ with student-specific information about problems, skills, and inputs that might (i) affect college completion and (ii) only be known by one teacher. These factors include: whether the student is being bullied, has been in a fight, participated in the science fair, finds classes interesting, participated in a “test prep” course for college applications, and whether the parent thinks the student might have an un-diagnosed learning disability and are summarized in Table S5 in Appendix A. Rows 4-9 of Table 6 show that none of these variables significantly predict disagreements in teacher expectations. Together, the tests discussed in this section and reported in Table 6 suggest that the identifying assumption is valid: teacher disagreements are not driven by factors that might directly affect educational attainment, but are only observed by one teacher.

3.2.2 Rank Condition and Additional Measurements

As written, the model described in equations (3)-(6) in the previous section is not econometrically identified in that there are not enough measurements to identify all model parameters. There are two reasons. First, we cannot identify latent factors with discrete outcomes absent further data. Second, the two expectation equations, which are used as imperfect measurements of student ability, are also included as regressors (via the b) in the outcome equation. One way to achieve identification is to place additional restrictions on parameters as in Heckman et al. (2006) and replace the probit functional forms with linear probability models (LPM). In Appendix B, we show that if we restrict $\gamma_E = \gamma_M \equiv \gamma$ and $\phi_E = \phi_M \equiv \phi$, we obtain an identified system of equations, and that the resulting LPM estimates of the impact of bias remain similar to the average partial effects (henceforth: APE) reported in Table 7.

Parameter restrictions are a useful alternative when there are not obvious exclusion restrictions on additional data, i.e., variables that only enter either the expectations or the outcome equations, but not both. Typically, it is difficult to defend such exclusions. Fortu-

illustrative, example. In the show, a student confides in Pastor Tim that her parents are Russian spies. This information would likely affect both Pastor Tim’s expectations and the student’s educational attainment. If other teachers are unaware that the student’s parents are Russian spies, θ will fail to fully capture this relevant information, and model estimates will be subject to omitted variables bias. Of course, the absurdity of this situation highlights the low likelihood that such problems plague the ELS data.

nately, two exams (a math and a reading test) were administered to all ELS-2002 students. Results from these exams were not revealed to students or teachers. Therefore, the exams can be used as additional (mis)measurements of student ability, but do not enter into the student outcome equation once we have conditioned on θ_i . In other words, scores on these exams should only be associated with educational attainment because they reflect factors that would likewise affect college completion, but not because teachers observe them.²⁶

We also control for 9th grade grades in the outcome equation, allow grades to affect teacher expectations, and also use grades to identify θ_i . This is useful for a couple of reasons. First, we might be concerned that math and reading test scores do not contain the full set of skills that teachers observe, in which case there would be bias in the impact of teacher forecast error on y . Several papers (e.g., Cunha et al., 2012) argue that test scores might not measure non-cognitive skills, such as motivation or grit, but that grades would. Moreover, we do not want to see grades as independent of θ , which requires that we model their relationship with θ . Finally, we want to illustrate how teacher bias can be due to a mis-reading of the mapping of skills to outcomes, where some skills are observed by the econometrician and some are not.

Formally, we add three measurement equations:

$$S_{ji} = c_{Sj} + \phi_{Sj}\theta_i + e_{Sji}, j \in \{E, M\} \quad (8)$$

$$G_i = c_G + \phi_G\theta_i + e_{Gi} \quad (9)$$

where S_j is the test score in subject j . In the equations, e_{SEi} and e_{SMi} follow normal distributions with $N(0, \sigma_{S,j})$ for $j \in \{E, M\}$, independent across i and j . Further, e_{Gi} are assumed to be independent of e_{SEi} and e_{SMi} and to follow a truncated normal distribution with mean 0 and standard deviation σ_G , where the upper and lower cutoff values are equal to the draw of e_{Gi} that equate GPA to 4.0 and 0, respectively. Appendix C shows formally that the addition of these three measurement equations identifies the system of equations (3)-(9).

²⁶To assess the validity of using these additional measurements, in Appendix B, we also estimate a version of the LPM model with the parametric assumptions on error terms used in our main model along with the additional data needed for identification of the main model. We show that estimates of γ in that model are nearly identical to estimates of the restricted non-parametric model described above. Similarity of results gives us some confidence in our approach of using these additional measurements to achieve identification of our main model.

3.3 Estimation

The econometric model is described in equations (3)-(9). We collect the parameters to be estimated into a vector denoted Ξ :

$$\Xi = \langle c, \sigma_\theta, \beta, \{\gamma_j, c_j, \phi_j, \beta_j, c_{j,D}, \phi_{j,D}, \beta_{j,D}, c_{S,j}, \phi_{S,j}\}_{j \in \{E,M\}}, c_G, \phi_G, \sigma_G \rangle. \quad (10)$$

We estimate Ξ using simulated maximum likelihood (Hajivassiliou and Ruud, 1994). In the inner loop of the estimation algorithm, we compute the likelihood for a particular set of candidate parameters, which are indexed by (g) and denoted $\Xi^{(g)}$. To calculate the log likelihood for a given set of candidate parameters $\Xi^{(g)}$, we first draw the latent factor K times for each individual i . We denote each draw $\theta_{ik}^{(g)}$.²⁷ For each $\theta_{ik}^{(g)}$, we use distributional assumptions on the error terms, additional candidate parameters, and data to calculate the likelihood contribution for teacher expectations ($P_{T_\tau}(T_{i,j}|\theta_{ik}^{(g)})$, $j \in \{E, M\}$). Next, for each draw, we calculate bias using equation (6). Then, we calculate the likelihood contribution for college completion, denoting the probability $P_y(y_i|\theta_{ik}^{(g)})$. Similarly, we compute the likelihood contributions for the test scores and for ninth-grade GPA, denoting these densities $f_E(S_{E,i}|\theta_{ik}^{(g)})$, $f_M(S_{M,i}|\theta_{ik}^{(g)})$, and $f_G(G_i|\theta_{ik}^{(g)})$, respectively. Using these components, we calculate the value of the likelihood for each draw of the latent factor $\theta_{ik}^{(g)}$ as:

$$\begin{aligned} L_{ik}^{(g)} &= P_y(y_i|\theta_{ik}^{(g)}) \times \prod_{\tau \in \{E,M\}} P_{T_\tau}(T_{\tau i}|\theta_{ik}^{(g)}) \\ &\times f_E(S_{E,i}|\theta_{ik}^{(g)}) \times f_M(S_{M,i}|\theta_{ik}^{(g)}) \times f_G(G_i|\theta_{ik}^{(g)}). \end{aligned} \quad (11)$$

After constructing $L_{ik}^{(g)}$ for each individual i and draw k , we then average $L_{ik}^{(g)}$ over the K draws for each individual. Finally, we take the log and then sum over all N individuals to obtain the log-likelihood: i.e., we compute:

$$l^{(g)} = \sum_{i=1}^N \log \left(\frac{1}{K} \sum_{k=1}^K L_{ik}^{(g)} \right). \quad (12)$$

In the outer loop, we repeat the inner loop for different sets of candidate parameters until the log likelihood function is maximized. We use quasi-newton methods to choose candidate

²⁷Prior to estimating, we draw a block matrix of size $N \times K$ from a standard normal distribution once and denote it Ψ , where N is the number of individuals in the sample and K is the number of simulation draws, set to 1,000. At each draw, $\theta_{ik}^{(g)}$ denotes the value of the latent factor for individual i and draw k . It is element (i, k) in Ψ multiplied by $\sigma_\theta^{(g)}$. This helps to avoid the so-called ‘‘chattering’’ effect, which can lead to different values of the likelihood function given the same parameters due to differences in random draws at each parameter set.

parameters.²⁸

4 Do Teacher Expectations Matter?

This section discusses the estimated model. Section 4.1 presents parameter estimates and average partial effects. Section 4.2 examines teacher biases, focusing on how biases differ by teacher and student race. Section 4.3 illustrates how the model explains black and white attainment gaps as a function of factors occurring prior to the tenth grade, but also as a function of how teachers use these factors to form expectations and how these expectations affect students through the mechanism of self-fulfilling prophecies. This exercise motivates analyses of policies, which are examined in Section 5.

4.1 Parameter Estimates and Average Partial Effects

Tables 7 and 8 report parameter estimates of the education and teacher expectation production functions defined by equations (3) and (5), respectively.²⁹ Column (1) of Table 7 reports parameter estimates for white students, and the estimated γ suggest that teacher expectations have positive, statistically significant effects on the probability that white students complete a 4-year degree.³⁰ The estimated β is positive and statistically significant, indicating that students with higher 9th-grade GPAs are significantly more likely to earn a four-year college degree than their counterparts with lower GPAs. This result is intuitive and provides a useful check of the model, since GPA is a known proxy for academic ability that predicts college completion (Bound and Turner, 2011). The magnitudes of these probit coefficients cannot be directly interpreted, so the bottom panel of Table 7 reports the APE of teachers' expectations, the main independent variables of interest, on the likelihood of earning a four-year degree.³¹ The APEs indicate that for white students, on average, the impact of either teacher changing from not expecting to expecting a college degree is about a 20 percentage point increase in the likelihood of the student completing a four-year degree. These effects translate into statistically significant elasticities of college completion with respect to biases of about 0.12. The effects of math and ELA teachers' biases are not

²⁸We also repeat the estimation algorithm for different sets of starting values to help ensure that we have not found a local maximum.

²⁹Table S6 in Appendix A reports the “nuisance parameter” estimates from measurement equation (9).

³⁰We refer to effects of bias and teacher expectations interchangeably since there is a 1:1 relationship between these constructs, by definition, in equation (5).

³¹Standard errors for the APE are computed via the delta method. The APE are evaluated at the mean value of θ , which is zero by construction.

significantly different from one another, and are remarkably similar in size to the corresponding linear 2SLS estimates for white students reported in columns (3) and (4) of Table 5. The similarity between these two approaches lends additional credence to the interpretation of these estimates as causal effects of teacher expectations on students' long-run educational attainment.

Column (2) of Table 7 reports parameter estimates for black students, and the estimated γ once again suggest that teacher expectations have positive effects on educational attainment. However, only the ELA teacher's expectation is statistically significant at traditional confidence levels, and this coefficient is similar in size to that for white students.³² The estimated β is once again positive and statistically significant, though smaller in magnitude than that for white students.

The variance and mean of θ , via the probit function, determine the objective probability (absent teacher bias and conditional on GPA) that a student will complete college. Consistent with realized educational outcomes, a comparison of columns (1) and (2) shows that the distribution of θ for black students is centered to the left of that for white students, and exhibits greater variance. This means that upon reaching the tenth grade, black students are already disadvantaged relative to their white counterparts in terms of college potential. Again, this does not reflect their ability, but instead captures racial disparities in the multitude of investments over the lifecycle, including factors such as school quality, neighborhood effects, and early childhood environments and resources. Our model is designed to separate the objective probability (which teachers use to form their expectations) from the impact of teacher expectations via self-fulfilling prophecies.

The bottom panel of column (2) shows that the APE of ELA teachers' expectations on the probability that black students earn a four-year college degree is strongly statistically significant and similar in size to the APE of ELA teachers' expectations on white students' educational attainment. The APE of math teachers' expectations on the probability that black students complete college is positive, but only about half as large and imprecisely estimated. The lack of precision may be partly due to the relatively small number of blacks in the sample. Nonetheless, the main implications of Table 7 are that (i) teacher expectations have a positive, arguably causal impact on college completion and (ii) the measurement error model yields estimates of these effects that are qualitatively similar to linear 2SLS estimates of the reduced-form equation (1).

Table 8 similarly reports the parameter estimates of the teacher expectation production functions. The first two columns report the parameter estimates for white students' ELA

³²However, the math and ELA γ are not significantly different from one another.

and math teachers, respectively. The production of teacher expectations for white students is broadly similar across subjects: the other-race teacher indicators are both statistically insignificant, as are their corresponding APE, which is consistent with the lack of a racial-mismatch effect on teachers’ expectations for white students in Gershenson et al. (2016). Also, intuitively, teachers’ expectations are increasing in both θ and 9th-grade GPA. The results for black students, reported in columns (3) and (4), are broadly similar. However, there is one notable difference: for black students, there are negative, significant effects of student-teacher racial mismatch on teachers’ expectations. This is again consistent with estimates reported in Gershenson et al. (2016). Specifically, pooled estimates of student-FE LPMs in Gershenson et al. (2016) find that racial mismatch reduces the probability that teachers expect a black student will complete a college degree by 0.09. However, when allowing the effect to vary by subject, the authors find that the racial-mismatch effect is about twice as large for math teachers (0.15) as for ELA teachers (0.07). This pattern, and the effect sizes, are remarkably similar to those reported in columns (3) and (4) of Table 8. That the measurement error model estimated here produces similar evidence regarding the impact of student-teacher racial mismatch on teachers’ educational expectations for black students, despite using a demonstrably different identification strategy and estimation procedure, cross-validates the measurement error model and lends additional support to the causal interpretation of the estimated impact of teacher expectations on educational attainment.

4.2 Race Differences in Teacher Biases

Thus far, we have documented an arguably causal relationship between teacher expectations and educational attainment and confirmed previous results suggesting that student-teacher racial mismatch reduces teachers’ educational expectations for black students. However, the results in Table 8 do not speak directly to long-debated questions about whether, to what extent, and in what direction teacher expectations are biased. The model developed in section 3.1, and specifically equation (6), provide answers to these questions. Figure 4 plots kernel density estimates of the distributions of the biases in teachers’ expectations separately by student race, subject, and student-teacher race congruence.³³

Panel A shows the distributions of ELA teachers’ biases. For both same- and other-race ELA teachers of both white and black students, the average bias is positive. In other words, teachers are overly optimistic on average, which is consistent with patterns observed in the

³³Another way to illustrate these differences is using contour plots, which are presented in Figure S1 in Appendix A. These plots (heat maps) depict higher concentrations as brighter colors.

raw ELS data documented in Table 1 and in Figure 2. Also, for both same- and other-race ELA teachers the average amount of bias is similar for both white and black students. However, the average positive bias (over-optimism) is slightly larger for black students when evaluated by a black teacher. This is consistent with evidence of smaller effects of student-teacher racial mismatch on ELA teachers' expectations for black students. The similarity in means is somewhat misleading, however, as it obfuscates more pronounced differences across the distribution. Specifically, there is more mass at zero bias for blacks than for whites, as many teachers accurately predict that black students will not complete college, and this is true for both same- and other-race teachers. There is similarly more mass at one (the upper bound of bias) for blacks than whites, which is due to both same- and other-race teachers being more likely to expect black students to complete college, even when the objective probability of them doing so is nil. White students, meanwhile, are more likely than blacks to receive positive bias in the range of about 0.1 to 0.7, which means that both same- and other-race teachers are more likely to give white students the "benefit of the doubt" and expect a four-year degree when their objective probability of completing college is in the 30-90% range.

Panel B of Figure 4 similarly plots the distributions of math teachers' biases. Many of the qualitative patterns observed in Panel A for ELA teachers are present here: biases are positive on average for all students, blacks are more likely than whites to receive zero bias, and on average, black students receive more positive bias (over-optimism) than white students when evaluated by black teachers, while the opposite is true for white teachers' expectations. However, differences in the bias distributions of same- and other-race math teachers are significantly more pronounced than the corresponding differences for ELA teachers. This is to be expected, given the result in Table 8 that the effect of racial mismatch on expectations is significantly larger for math teachers than for ELA teachers. Indeed, these mean differences are driven by a notable increase in the frequency of objectively correct (zero-bias) expectations and a flattening of the right tail of the bias distribution for other-race teachers' expectations for black students. This raises a nuanced, but important point: other-race math teachers' expectations for black students may be more accurate (less biased) than those made by black math teachers. However, this accuracy has the potential to propagate racial gaps in educational attainment, since we have shown that high expectations, even overly optimistic ones, have an arguably causal positive impact on college completion. The results in Figure 4 indicate that on average, all teachers are too optimistic about students' college-completion potential, but the degree of overoptimism is greater for black students assessed by black teachers relative to white teachers. We explore these ideas in greater detail below.

4.3 Race Mismatch and Teacher Expectations

We have demonstrated a causal impact of teacher expectations on student outcomes along with racial differences in the production of bias. However, we have yet to investigate how these two mechanisms interact and contribute to the racial gap in college completion. We begin to do so here, by noting that the model distinguishes between three types of racial differences that can influence racial gaps in educational attainment:

1. Initial conditions, including ninth-grade GPA and the latent factor θ_i , which combine to identify the objective likelihood of college completion (net of the impact of bias) at the time tenth-grade teachers form expectations.
2. The mapping between initial conditions and teacher expectations governed by the parameters in equation (5), i.e., racial disparities in the teacher expectations faced by students with the same θ_i and G_i
3. The production function of student outcomes governed by parameters in equation (3).

Figure 5 illustrates how each of these factors contributes to racial disparities.³⁴ The figure plots the CDF of the probability that black and white students will obtain a four-year college degree, assuming that all students have white teachers.³⁵ In the upper-right panel, we plot the objective distributions for black and white students. Immediately apparent are large gaps between blacks and whites produced by the model, which occur across the distribution.

In the upper-right panel of Figure 5, we simulate the black-white college completion gap under the counterfactual in which blacks are assigned the same initial conditions as whites, i.e., the same distribution of θ_i and of G_i . Not surprisingly, this closes much of the attainment gap, as many of the differences in the distribution of educational attainment arise from factors occurring prior to the tenth grade. Still, even with the same initial conditions, black students do not face the same distribution of college completion as white students. This means that some of the gap can be explained by how initial conditions map to expectations along with racial differences in how expectations produce outcomes.

One interesting feature of the upper right panel of Figure 5 is that black students with initial conditions suggesting a low probability of college completion might do better than their white counterparts if assigned the same initial conditions. The reason is that some

³⁴For each counterfactual simulation, this is done by drawing e_{G_i} , e_{E_i} , e_{M_i} , and θ 100,000 times using the distributional assumptions outlined in subsection 3.2.2 given our parameter estimates and simulating GPA, as well as ELA and math teacher expectations using equations (5) and (9). The probability that black and white students will obtain a four-year college degree is then calculated using equation (3).

³⁵We consider the implications of assigning more black teachers to black students in Section 5

black students with lower initial conditions may face higher positive bias. This can be seen in Figure 4, where black students are more likely to face optimistic teachers. Nonetheless, towards the upper end of the distribution, whites outperform blacks despite having the same ninth-grade GPA and the same objective probability of completing college. Again, since θ_i does not represent innate ability, these results suggest that two students enter the tenth grade having the same objective probabilities (net of bias) of finishing college might experience different outcomes. This discrepancy is due to racial differences in the production and impact of biases, which thus exacerbates existing gaps.

To illustrate this point, the lower-left panel of Figure 5 shows what happens if black and white students not only have the same initial conditions, but also the same mapping from initial conditions to teacher expectations. This has a relatively small additional impact on the gap, which can be seen in the lower right panel, where both counterfactuals are simulated. Notice, for individuals with relatively low or relatively high objective probabilities of college completion, the impact of the production of teacher bias is nearly zero. In fact, some black students in the lower tails are harmed if they face the same production of bias as white students. This is because black students with low θ_i tend to face higher expectations from white teachers. For black students in the middle of the distribution, however, facing the same mapping from initial conditions to teacher expectations as whites is helpful in promoting college completion. This finding is consistent with the distributions of bias plotted in Figure 4, which indicate that white students who begin with objective probabilities of college completion that are neither very high nor very low are more likely to be given the “benefit of the doubt” than are black students. Given that expectations matter, this can raise the attainment gap through self-fulfilling prophecies.

The lower right panel of Figure 5 also illustrates that the remainder of the gap is closed when blacks counterfactually face the same education production function as whites (governed by the parameters in equation (3)). Part of the production function difference is due to differences in γ , particularly differences in math teachers’ γ s across races. Another difference is in β , which may reflect disparities in school quality.³⁶ In general, Figure 5 demonstrates that most of the attainment gap between blacks and whites arises from factors that occur prior to our observing them in the tenth grade, which is not surprising and underscores the importance of interventions in early-childhood and primary-school education. Still, initial conditions do not account for the entire gap, which is concerning since it means that teacher expectations widen the gap. This is due to racial differences in the impact of bias on outcomes, but also due to differences in the production of bias. In the following section, we ask whether policies that affect the production of bias can reduce the black-white educational

³⁶Indeed, if black students face white γ , but different β , a small gap remains.

attainment gap.

5 Policy: Teacher Diversity versus Teacher De-Biasing

In this section, we discuss two counterfactual simulations designed to assess the impact of policies that modify the expectations faced by black students. We treat initial conditions θ_i and G_i as given, and therefore not as policy relevant, since our focus is on how teacher expectations respond to those conditions and ultimately affect student outcomes. Of course, these initial conditions are not fixed and can likely be shaped by other earlier interventions such as class size reductions (Dynarski et al., 2013), improved teacher quality (Chetty et al., 2013), and early childhood investments (Currie, 2001; Heckman, 2006). However, the current study’s aim is to assess whether changes in the production and impact of bias in secondary school settings can affect the black-white college completion gap.

We consider two policies, both of which can be evaluated using our model: hiring more black teachers, thereby increasing the probability that students of all races have a black teacher, and modifying how white teachers form expectations about black students. We operationalize the latter by imposing that white teachers, for a given θ_i and G_i , form “race blind” expectations for students. A crucial caveat to our analysis in this section is that we cannot make welfare statements using our model. For example, we have little data on the total costs of hiring more black teachers or of de-biasing white teachers. Moreover, our analysis considers the impact of these policies on college completion, which may overlook important costs if these policies induce a subset of individuals to try college and then fail out prior to completing a four-year degree. Though we discuss some evidence below that this does not appear to be the case, it is an important potential drawback to policies that raise relative expectations for black students.

We motivate our counterfactual simulations by simply plotting teachers’ expectations for black students as a function of θ_i while making different assumptions about how their expectations are formed. The top panels of Figure 6 show how white ELA and math teachers’ expectations change when we de-bias white teachers (i.e., when for a given θ , the black student receives the expectation normally given to a white student). It is immediately apparent that not all black students are helped by such a policy. Indeed, at low levels of θ white teachers have higher expectations for black students than for white students. However, at high levels of θ , black students benefit from this policy. This is consistent with the distributions of bias presented in Figure 4. The policy-relevant implication here is that de-biasing white teachers in this fashion would likely hurt some black students. Therefore, in

the formal policy simulation, we impose that white teachers’ expectations take the envelope of the two curves.

The bottom panels of Figure 6 show how the expectations of ELA and math teachers for black students change when the expectation is formed by a black—rather than white—teacher. Among ELA teachers there is a muted increase in expectations at all levels of θ of hiring more black teachers. For math, the effect is much larger due to the larger impact of racial mismatch on math teachers’ expectations. Importantly, white students are not hurt by this policy, as shown in the corresponding Figure S2 in Appendix A for white students.

In Figure 7, we directly compare de-biasing to hiring more black teachers. These “equivalent policy lines” report the combinations of de-biased and black teachers necessary to maintain the black college completion rate. Both the math and ELA teacher lines are upward sloping, which simply means that de-biasing white teachers and increasing the probability that black students have black teachers both increase black college completion on average. Both lines are steeper than the 45-degree line, indicating that raising the probability that a black student faces a black teacher is more effective at achieving college graduation for a given number of black students in relation to de-biasing an equivalent percentage of white teachers. Interestingly, the slope of the line is steeper and to the left for black math teachers. This means that to achieve the same effect of de-biasing a given number of white teachers, fewer black math versus ELA teachers would need to be hired. This is because of the relatively high expectations that black math teachers have for black students versus white math teachers. Of course, the similarity of the lines and slopes for math versus ELA teachers shows that hiring more black ELA teachers is also a policy worth considering. Nonetheless, this result underscores the need to identify the inputs and interventions that promote black student success in STEM fields and highlights the policy-relevance of black-white achievement gaps in STEM fields (Anderson and Kim, 2006; Arcidiacono et al., 2016; Harper, 2010).

Figure 7 compares the two policies as mutually exclusive interventions. In reality, they likely would not be. Policy makers might consider mixtures, such as simultaneously hiring more black teachers and attempting to de-bias white teachers. To understand how these two policies interact, we use the production function in equation (3) to plot isoquants in Figure 8. Specifically, for different combinations of de-biasing and hiring (e.g., de-bias 25% of white teachers and set the probability that black students face black teachers at 30%) we use the model to simulate college completion 100,000 times. Next, we assess which combinations of policies lead on average to the same probability of college completion. We plot resulting isoquants where the two policies have the same impact as de-biasing zero white teachers and setting the probability that black students face black teachers at 5 equidistant points along the distribution: $1/6$, $2/6$, $3/6$, $4/6$ and $5/6$. The proportion of black college graduates

is written on each isoquant. Plotted isoquant slopes are determined by the number of de-biased white teachers needed to keep the proportion of black college graduates constant if the proportion of black teachers is reduced. Finally, we construct these isoquants separately for each quartile of the distribution of θ since we know that these policies have different effects on individuals with different objective probabilities of completing college.

The four panels of Figure 8 highlight the heterogeneity by θ in the tradeoffs between the two policies. At one extreme, panel A shows that for students in the lowest quartile, de-biasing white teachers has no effect, as evidenced by the vertical isoquants. This is because white teachers tend to have higher expectations for students with low objective probabilities of completing college. Since the policy we consider takes the maximum of actual versus simulated expectations, the de-biasing policy literally does not affect students in the bottom quartile. Hiring more black teachers has some effect, though it is modest: increasing the fraction of black teachers from $1/6$ to $5/6$ raises the probability of college-going from 3.7% to 3.9%. This is troubling, as it shows that students with low objective probabilities of completing college degrees by the time they reach the tenth grade are difficult to help, at least via changing teachers' expectations. This underscores the limits of the policies we are considering here and the importance of interventions for students earlier on, as well as outside the traditional school setting.

Panel B of Figure 8 considers the second quartile. For this group, de-biasing of teachers seems to have some effect, though it is small. De-biasing all white teachers is equivalent to raising the proportion of black teachers from about 12% to about 16%. Panel C shows that de-biasing white teachers (compared to hiring more black teachers) becomes increasingly effective at increasing black-student graduation rates among students who already have relatively high objective probabilities of graduating, as the marginal rate of substitution is about 2.1. For example, to raise the probability of college completion from 33.9% to 34.6%, hiring practices would need to increase the likelihood of facing a black math teacher from 15% to 32%. Alternatively, the proportion of debiased white teachers would need to rise from 32% to 68%. The isoquant illustrates that some mixture of the two policies would also work, where linearity is due to the specification of the production function. Moreover, for individuals in the third quartile, policies become more effective, raising the graduation probability from 33.9% to 36.6%.

Among individuals with the highest objective probability of completing college (panel D of Figure 8), it is apparent that (i) policies are relatively more effective in general, raising college completion rates from 62.9% to 65.2% and (ii) the relative productivity of de-biasing white teachers rises, as the MRS is now about 1. The reason is that white teachers have especially low expectations for black students with high initial conditions in comparison

to white students with the same initial conditions. In other words, white teachers tend to underestimate the potential of black students relative to white students, particularly for black students with high objective probabilities of earning a college degree. This is concerning, as the black students with the most college potential face the largest penalties via teacher expectations. Panel D also shows that hiring more black teachers would be beneficial. For example, raising the probability that a black student faces a black math teacher from 15% to 35% raises the college completion rate from 62.9% to 63.5%. Recall, this result conditions on the objective probability of college completion for students in tenth grade. Similar interventions in earlier grades could have even stronger effects.

6 Conclusion

We provide a framework to estimate the causal impact of teacher expectations on student outcomes. Our approach jointly estimates education and teacher expectation production functions using data from a nationally representative longitudinal survey of U.S. high school students. The identification strategy leverages insights from the measurement-error literature and a unique feature of these data: two teachers provided their educational expectations for each student. Our analysis suggests that teacher expectations are not just accurate forecasts of student outcomes, but that biases also influence outcomes by becoming self-fulfilling prophecies. Moreover, we find that the production of white teachers' expectations places black students at a disadvantage. For a given objective probability of college completion, white teachers are less optimistic about black students. Policies that would put black students on the same footing as white students in terms of how teacher expectations are formed could narrow attainment gaps, though only slightly. Not surprisingly, large gaps in the objective probability of college completion exist by the time students reach the tenth grade and these would need to be addressed with earlier interventions.

Our results suggest several areas for future research. One extension would be to study specific mechanisms linking teacher beliefs to outcomes. Moreover, it would be straightforward to extend our analysis to consider variation by gender, family income, or other factors in how teacher expectations diverge from objective probabilities. Another set of extensions would use our framework for different populations or contexts. One possibility would be to examine the role of biased beliefs for students in earlier grades to assess whether they have stronger, or longer-lasting, effects. More generally, our approach could be used to assess the role of expectations in driving behavior in other contexts where individuals are tasked with making economic decisions under uncertainty. However, doing so using our framework would

require data on multiple reports of expectations of a given outcome. Thus, the approach we develop here along with our results suggest that collecting multiple reports of subjective expectations could be used to identify causal effects of expectations on outcomes.

Observations	6060	6060	6060	6060	6060	6060	6060	3970	610
R^2	0.22	0.22	0.28	0.28	0.33	0.35	0.44	0.47	0.63
Adjusted R^2	0.22	0.22	0.28	0.28	0.32	0.35	0.37	0.37	0.31

Note: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. The dependent variable is a binary indicator equal to one if the student completed a four-year college degree or more, and zero otherwise. Parentheses contain standard errors that are robust to clustering at the school level. These are OLS estimates of Equation (1). Student socioeconomic status (SES) controls include indicators for household income and mother's educational attainment as well as indicators for student race, sex, and if a language other than English is spoken at home. Teacher controls include teacher race and gender dummies, years of experience, and whether or not the teacher majored in the subject he or she teaches. School FE refers to school fixed effects.

Table 4: Transition Matrices of Disagreements in Teacher Expectations

Math Teacher Expectation	English Teacher Expectation			Total
	HS or Less	Some College	Bachelor's or More	
All Students (N = 6060)				
HS or Less	7.12	4.79	1.62	13.54
Some College	4.32	9.90	9.27	23.49
Bachelor's or More	1.62	8.36	52.99	62.97
Total	13.06	23.06	63.88	100.00
White Students (N = 3970)				
HS or Less	5.47	4.16	1.21	10.82
Some College	4.18	9.56	9.09	22.83
Bachelor's or More	1.33	8.31	56.71	66.35
Total	10.97	22.02	67.00	100.00
Black Students (N = 610)				
HS or Less	13.18	8.07	2.63	23.88
Some College	7.08	12.52	12.03	31.63
Bachelor's or More	2.63	8.07	33.77	44.48
Total	22.90	28.67	48.43	100.00

Note: HS is high school. Each entry reports the percentage of observations that fall in the particular math teacher expectation-ELA teacher expectation category.

Table 5: 2SLS Estimates of Effect of Expectations on Educational Attainment

Hausman Test p-value		0.05		0.27		0.81
Over-identification p-value		0.59		0.48		0.77

Note: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. The dependent variable is a binary indicator equal to one if the student completed a four-year college degree or more, and zero otherwise. Parentheses contain standard errors that are robust to clustering at the school level. The first two rows present OLS and 2SLS estimates, respectively, of Equation (1), for the analytic sample for which all instruments are observed. All regressions control for student race, sex, 9th-grade GPA, math and ELA scores, household income, indicator for single parent family, mother's educational attainment, school fixed effects, and teacher race, sex, and educational attainment.

Table 6: Testing the Exogeneity of Teacher Bias

Regression No.	Variable	Estimates
1	9th-grade GPA	-0.0723*** (0.0097)
2	$ S_E - S_M $	0.0023 (0.0014)
3	$ S_E - S_M $	-0.0005 (0.0031)
	$ S_E - S_M ^2$	0.0002 (0.0002)
4	S Ever Bullied	0.0012 (0.0147)
5	S Got in Fight	-0.0023 (0.0205)
6	S Participated in Science Fair	-0.0126 (0.0191)
7	S finds class interesting	-0.0032 (0.0130)
8	S Ever in college prep	0.0160 (0.0147)
9	P thinks S has disability	-0.0376 (0.0243)

Note: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. $N = 6060$. Each row reports the coefficient(s) of interest from a unique regression. When necessary, a dummy for “variable of interest is missing” is included in the regression. These “missing” indicators are never statistically significant. S is student and P is parent. S_E and S_M are ELA and math standardized test scores. All regressions control for student race, sex, 9th-grade GPA, household income and mother’s educational attainment, indicators for single parent household and if a language other than English is spoken at home, and school fixed effects. In regression 3, the quadratic terms are jointly insignificant (F-stat = 1.63, p -value= 0.20.)

Table 7: Education Production Function Estimates

	Whites	Blacks

b_M	0.13*** (0.02)	0.08 (0.05)
N	3970	610

Note: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. Parameter estimates of equation (3) are reported. The dependent variable is a binary indicator equal to one if the student completed a four-year college degree or more, and zero otherwise. Standard errors are computed by constructing the Hessian of the likelihood function using outer product measure. To compute the outer product measure, we calculate two-sided numerical derivatives of the likelihood function for each estimated parameter. In each direction, the derivative is calculated by perturbing each parameter and then computing the likelihood. Standard errors for the average partial effects (APE) and elasticities are calculated using the delta method.

Table 8: Teacher Expectation Production Function Estimates

	Whites		Blacks

N	3970		610	

Note: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. Parameter estimates of equation (5) are reported. Standard errors are computed by constructing the Hessian of the likelihood function using outer product measure. To compute the outer product measure, we calculate two-sided numerical derivatives of the likelihood function for each estimated parameter. In each direction, the derivative is calculated by perturbing each parameter and then computing the likelihood. Standard errors for the average partial effects (APE) are calculated using the delta method.

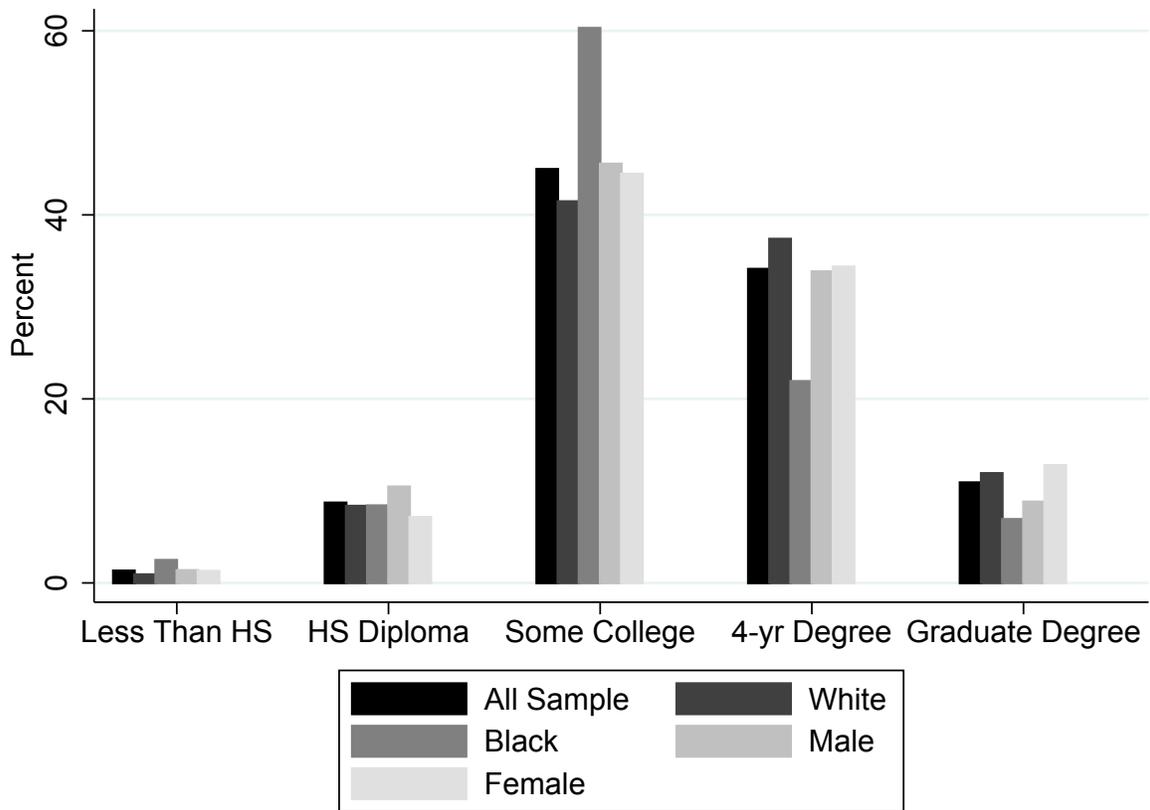

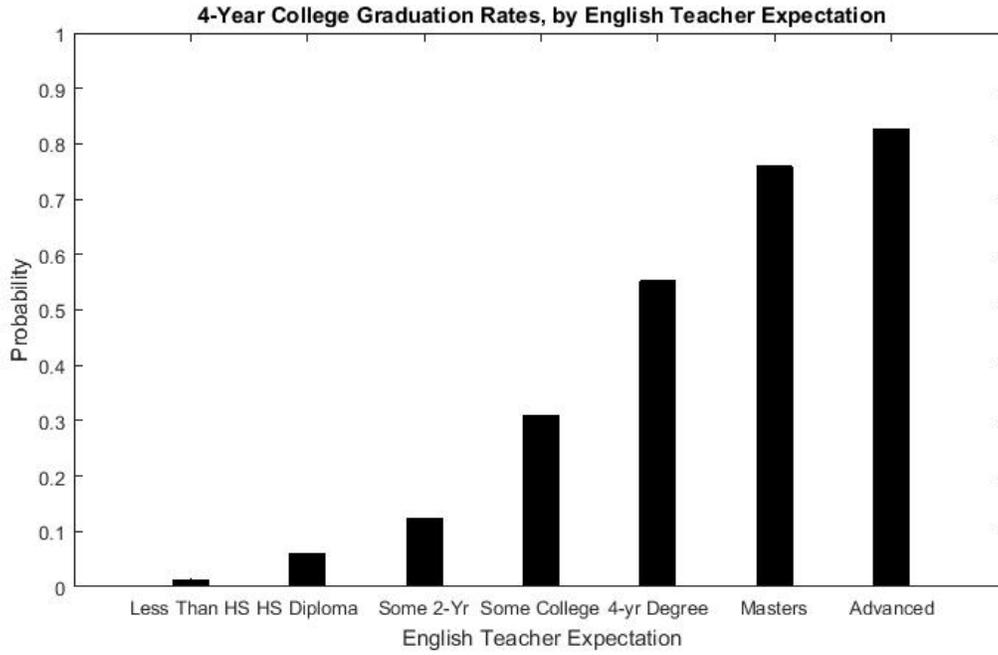

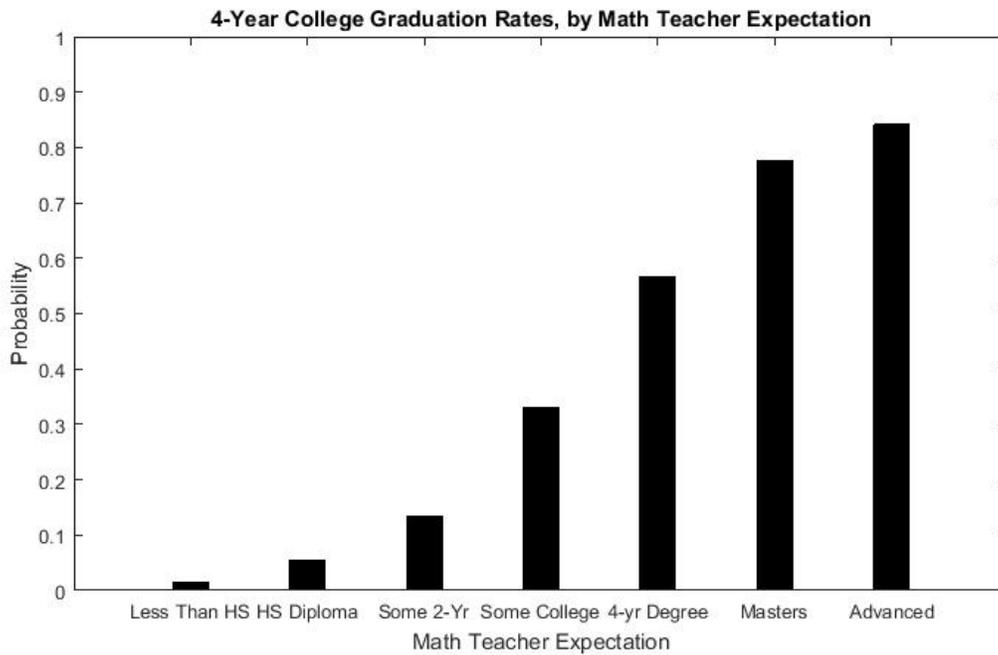

Figure 1: EDUCATIONAL ATTAINMENT, BY SUBGROUP. Histogram of percentage of subsample of students who fall in the given educational attainment category is plotted. HS is high school. Graduate degree includes masters, Ph.D., or professional degrees

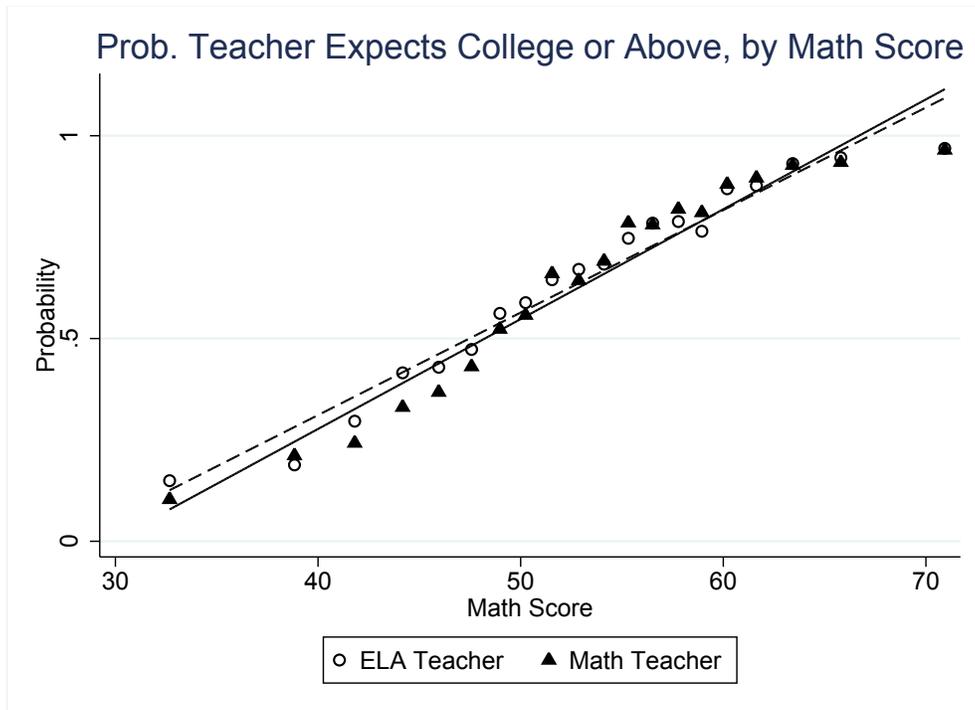

(a)

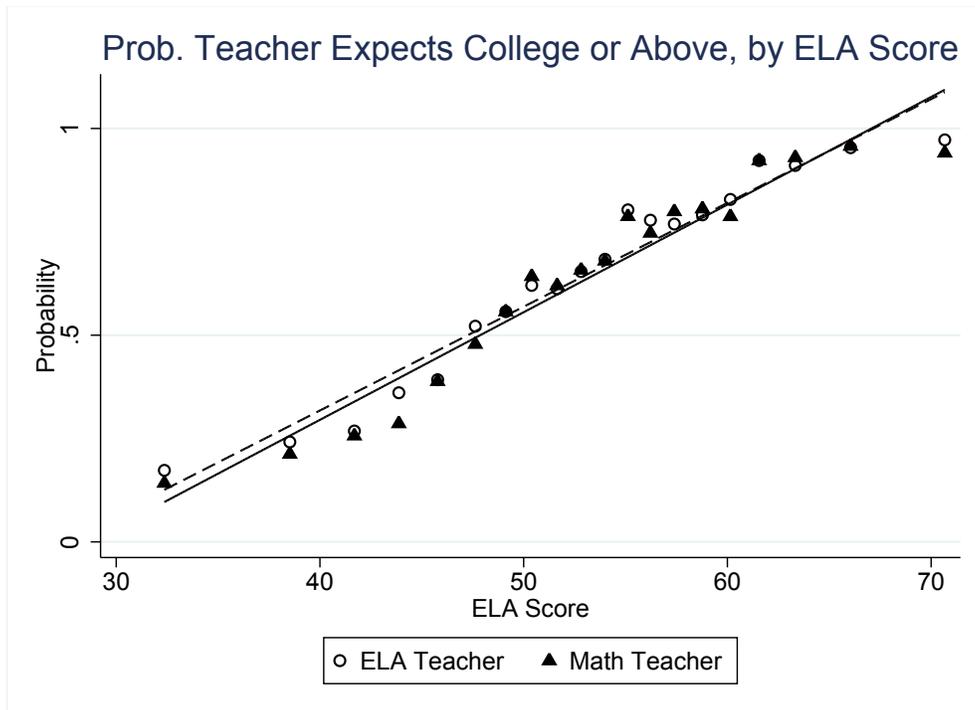

(b)

Figure 2: TEACHER EXPECTATIONS AND STUDENT OUTCOMES. Panel 2(a) shows the percentage of students who complete a four year college degree by ELA teacher expectations. Panel 2(b) plots respective percentages by math teacher expectations.

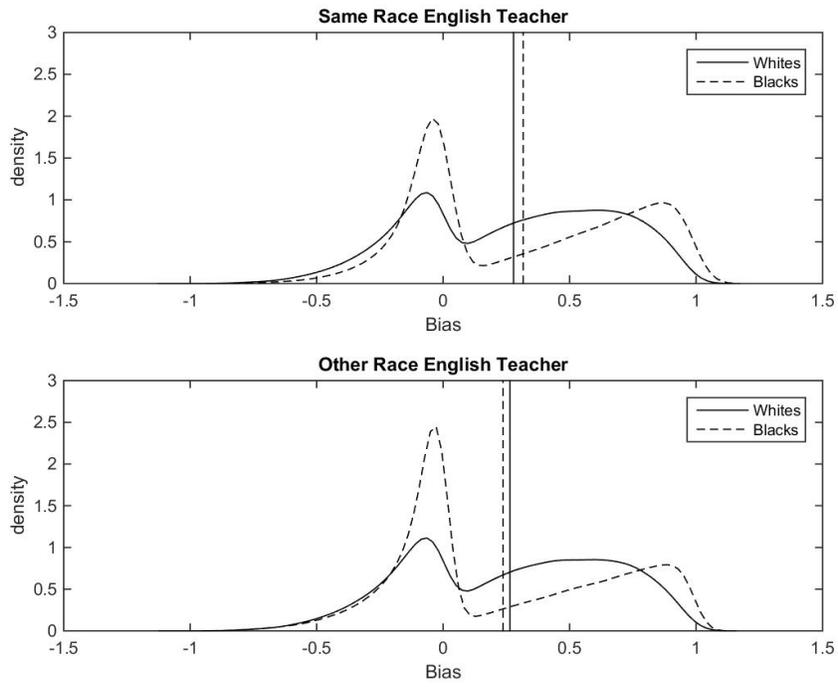

(a)

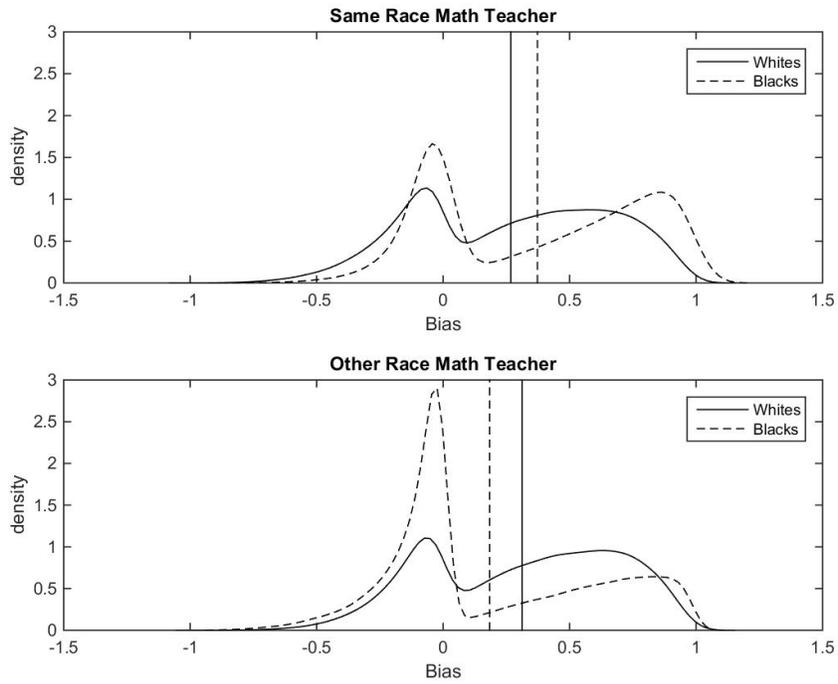

(b)

Figure 3: MATH AND ELA SCORES AND TEACHER EXPECTATIONS. Binned scatterplots, along with the lines of best fit for ELA (dashed lines) and math teacher expectations (solid lines), by math and ELA score, respectively.

(a)

(b)

Figure 4: DISTRIBUTION OF BIAS BY STUDENT RACE. PDFs of teacher bias are plotted. Vertical lines represent mean bias. Panel 4(a) shows distribution of bias for white and black students with same and other race ELA teacher. Panel 4(b) shows respective distributions of math teacher bias. Bias is defined in equation (6).

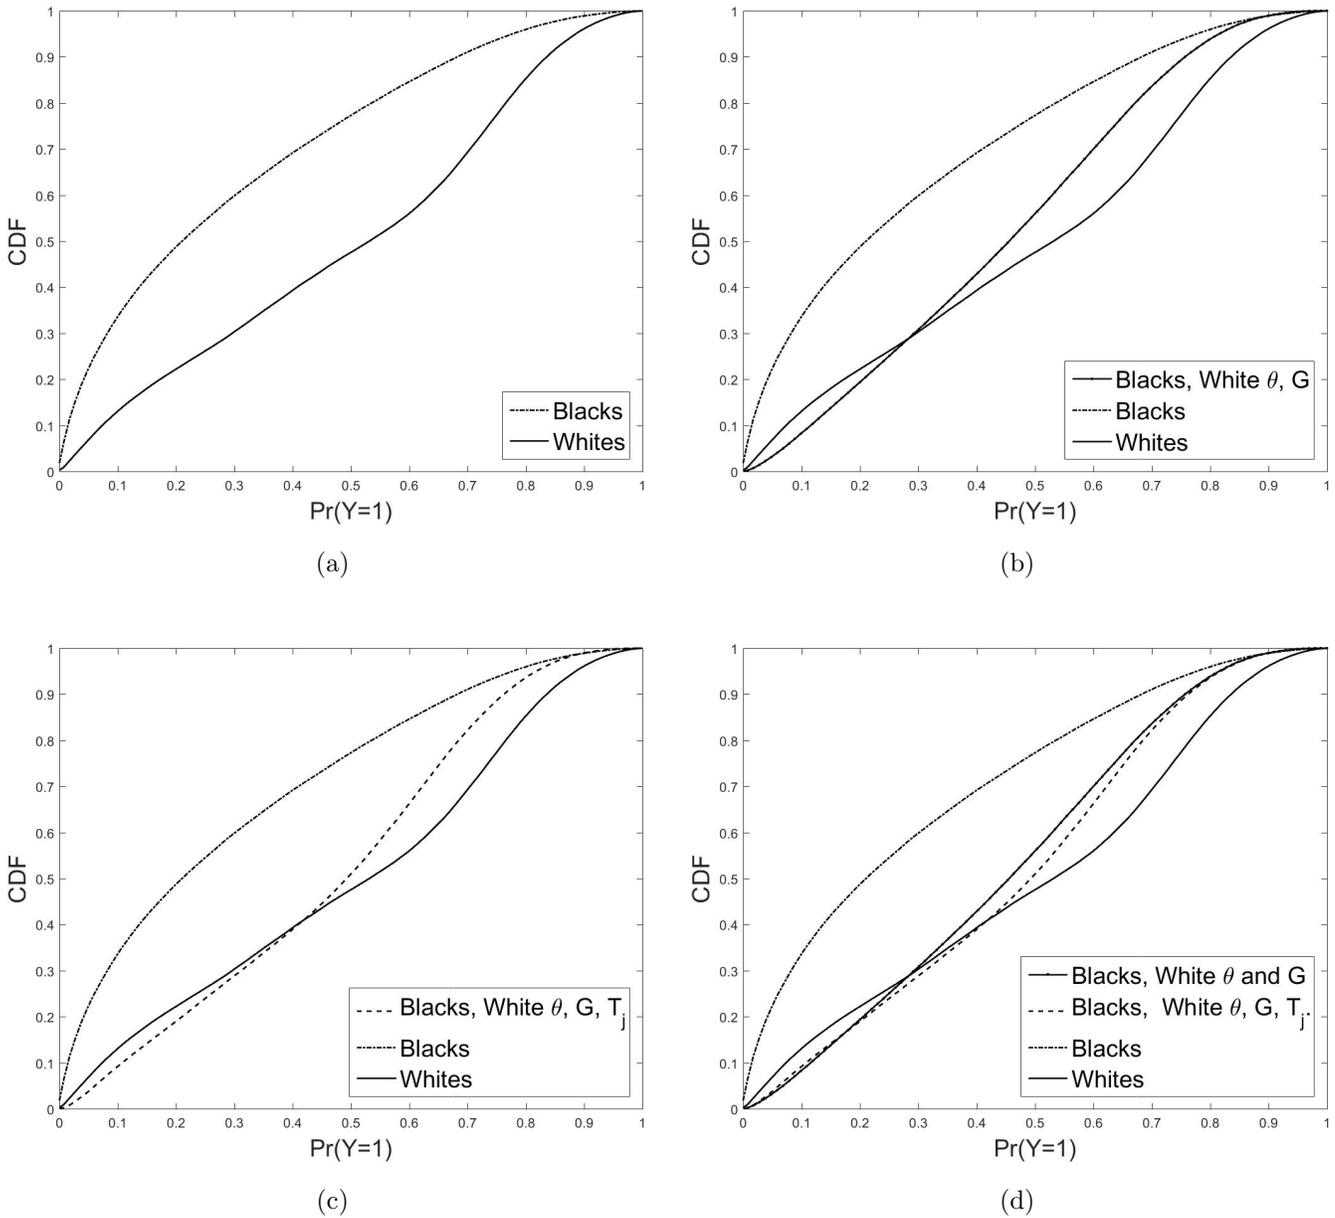

Figure 5: CDFs of COLLEGE COMPLETION PROBABILITY FOR STUDENTS OF WHITE TEACHERS. Black and white denote student race. θ is the latent factor that measures the objective probability of completing college (net of GPA and bias), G is 9th-grade GPA, T_j is the the expectation of the subject- j teacher, and Y is a binary indicator for college completion. Panel 5(a) plots the actual CDFs of $Pr(Y = 1)$ for black and white students who have white teachers. Panel 5(b) plots the distribution under the counterfactual in which black students have the same θ and G as white students. Panel 5(c) plots the distribution under the counterfactual in which black students face the same teacher expectation production function *and* the same θ and G as white students. Panel 5(d) combines the three previous plots. The largest difference between the two CDFs occurs at $Pr(Y = 1) = 0.50$, with the magnitude of difference being 0.05.

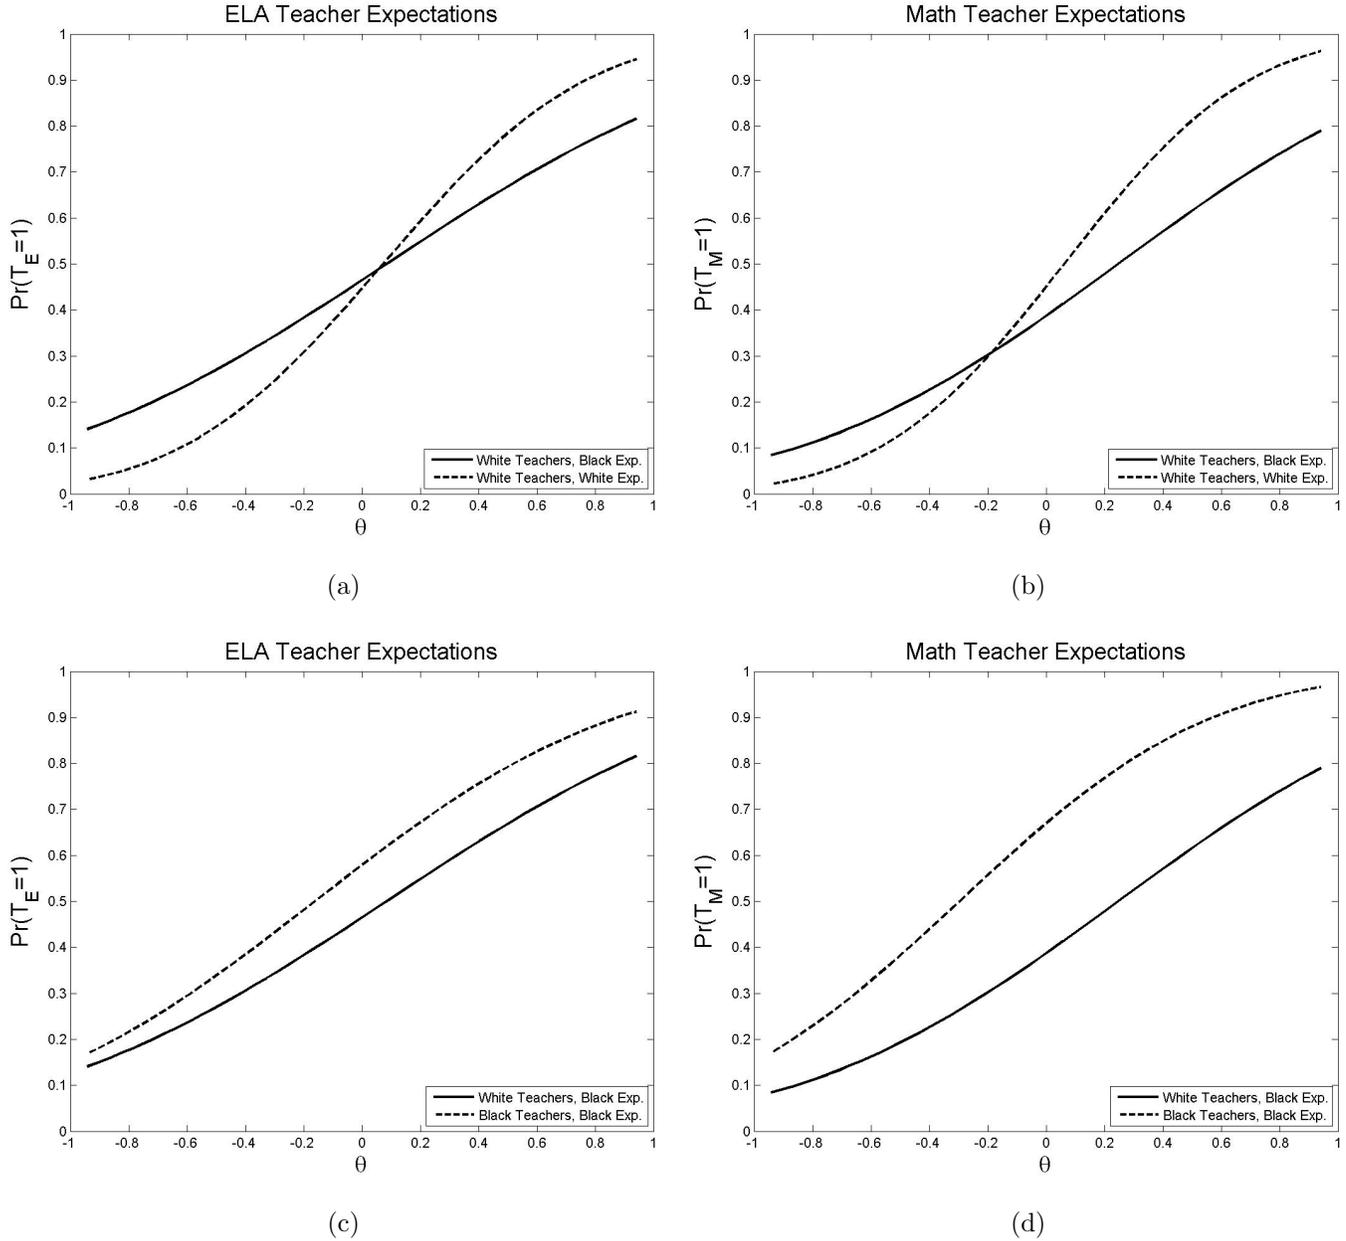

Figure 6: TEACHER EXPECTATIONS FOR BLACK STUDENTS. θ is the latent factor that measures the objective probability of completing college (net of GPA and bias) and T_j is the expectation of the subject- j teacher. Panel 6(a) shows how teacher expectations change when black students face the same expectation production function from white ELA teachers as white students. Panel 6(b) shows how the expectations change in the counterfactual scenario for math teachers. Panels 6(c) and 6(d), respectively, compare white and black ELA and math teachers' expectation for black students with given θ .

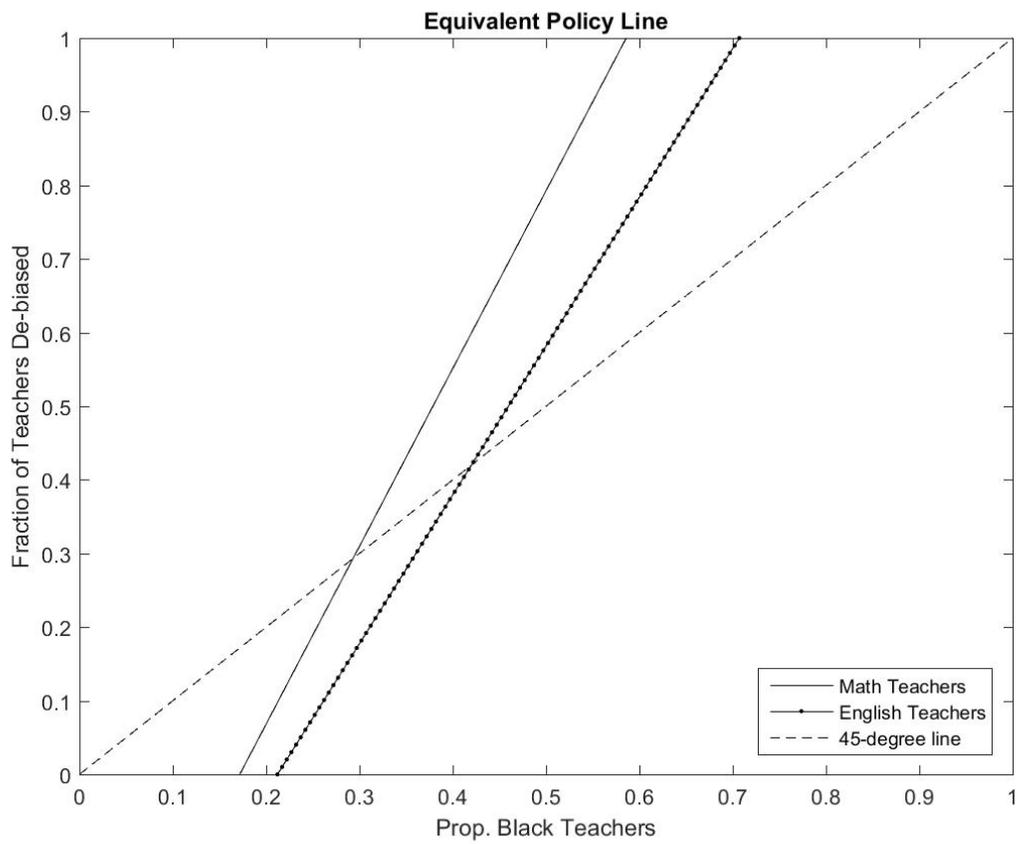

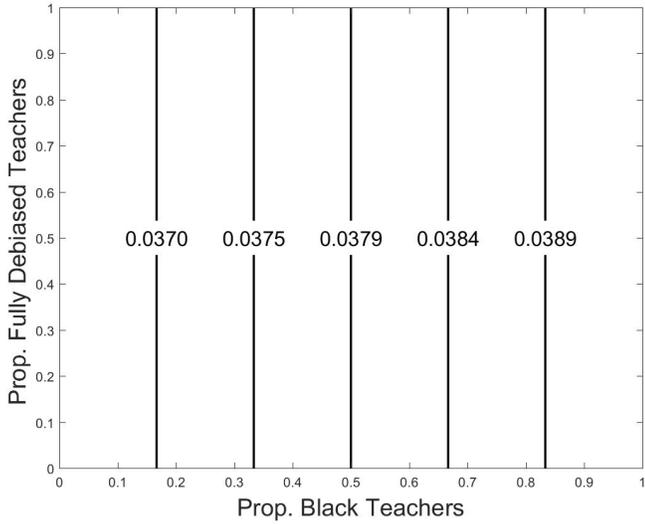

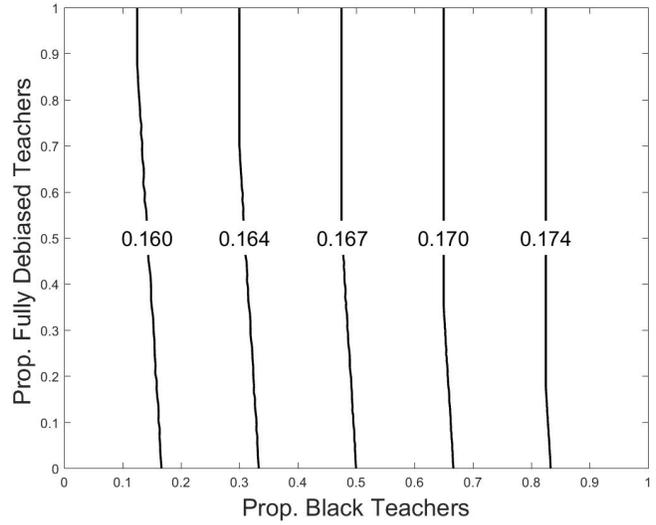

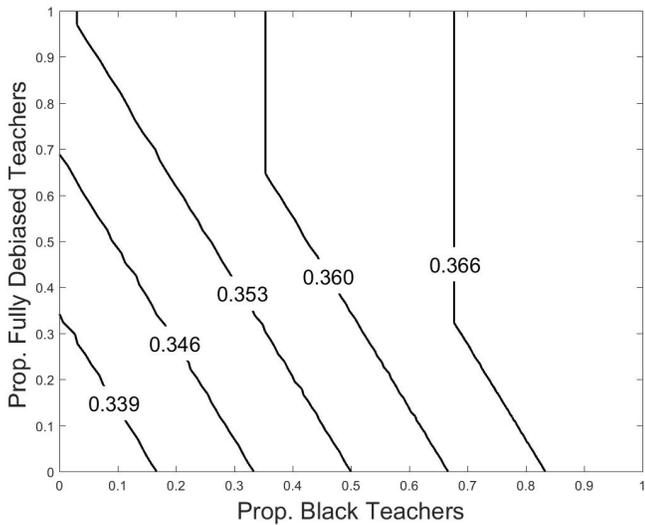

Figure 7: EQUIVALENT POLICY LINE. Level of de-biasing and hiring policies needed to achieve the same college completion rates for black students is plotted.

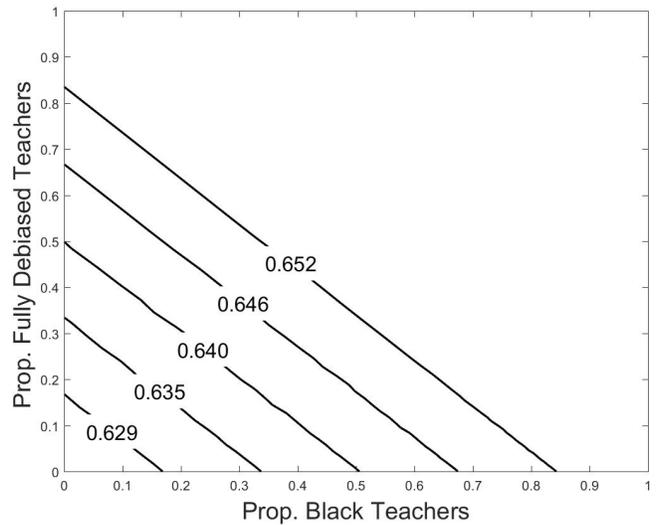

(a)

(b)

(c)

(d)

Figure 8: COLLEGE COMPLETION RATE ISOQUANTS. Isoquants with de-biasing and hiring more black teachers as two inputs and black students' college completion rates as outputs. Proportion of debiased teachers are calculated as the number of de-biased white teachers over the number of white teachers of black students when the proportion of black teachers is equal to 0. Panel 8(a) shows isoquants for black students in the first quartile in terms of θ . Panel 8(b) shows isoquants for individuals in the second quartile, and panel 8(c) and 8(d) respectively show the isoquants for individuals in third and fourth quartiles. Kinks occur when all white teachers of black students are debiased.
