Abstract

The aim of this paper is to examine the returns to education taking into consideration the existence of educational mismatches in the formal and informal employment of a developing country. For this purpose we estimate the standard Duncan and Hoffman's specification (so called ORU wage equation) at the mean and at different quantiles, using quantile regression estimation, and controlling for a rich set of observable individual and firm characteristics exploiting micro-data from Colombia. In both cases we correct for the endogeneity of sector participation. Our results show that the returns of surplus, required and deficit years of schooling are different in the two sectors. Moreover, they suggest that these returns vary along the wage distribution, and that the pattern of variation is not the same for formal and informal workers. In particular, we find that informal workers not only face lower returns to their education, but there is a second penalty associated with educational mismatches that puts informal workers at a greater disadvantage compared to their formal counterparts.

1. Introduction

A distinctive feature of almost all Latin American and the Caribbean labor markets is the existence and the persistence of a large informal sector. In fact, half of the employed population of this region worked in informal jobs at the end of the first decade of this century (ILO's 2011 Labour Overview). Informal employment embraces a variety of heterogeneous activities, such as self-employment entrepreneurs, salaried workers of large and small firms, and unpaid domestic workers. Informal employment generally involves that workers are trapped in unproductive activities, with inferior working conditions, lack of social security and lower earnings. A seemingly stylized fact, found in past studies about labor market segmentation, is that informal-sector workers, even if equally productive, are subject to lower remuneration than formal-sector workers. So even when more highly educated workers tend to be more productive than less skilled counterparts, education may not be the key for higher paying jobs if the labor market is segmented.

A number of explanations have been offered to explain why some earning-relevant characteristics, for example, education, are better rewarded in the formal sector than in the informal sector. An important bulk of these explanations is based on a segmented view of the labor market. For instance, the presence of extremely restrictive labor market institutions and strict regulation of entry into the formal sector could pose a possible cause, so that some workers that do not have access to the formal sector are forced to accept informal sector jobs characterized by inferior earnings (see Fields, 1975). However, several more recent studies postulate, for both firms and workers the decision of being formal turns out to be extremely costly, due to the non labor costs associated with health and pension contributions, payroll taxes, commuting subsidies, among others, which significantly increases the attractiveness of informal activities. Maloney (1999), for instance, introduces a standpoint in which workers may find informal-sector employment a desirable alternative, due to inefficiencies in the provision of public services, i.e. health and pension, or because their level of human capital do not fulfill the

requirements for performing formal jobs. In the last case, a wage penalty for informal-sector employment may be due to sorting, where those with low levels of human capital are also those more likely to work in the informal sector (Tokman, 1982). This type of sorting may result from the fact that firms in the informal sector have limited access to financing and employers choose to substitute physical capital for low-skill labor (see, e.g., Amaral and Quintin 2006).

However, none of the former studies have considered one aspect which can affect the wage gap between formal and informal workers, that is, the way workers match their acquire education to the one required to perform their job. One important feature that raises concern in developed countries is the existence of a discrepancy between the education attainment of workers and the skill requirements of jobs, commonly known as education-occupation mismatch (OCDE Employment Outlook 2011). The incidence and labor market effects of educational-occupation mismatch, especially over-education, have received increasing attention in the literature for developed countries (Germany, the Netherlands, Spain, the United Kingdom, Portugal, Hong Kong and the United States)¹. Recently some attention has also been paid for some developing countries (Mexico, Pakistan, India, the Philippines, Thailand and Colombia)². Several of these studies have shown that the incidence of education-occupation mismatch varies significantly with the method used to measure required education, hence over-education. However while the choice of the method can have an effect on the incidence of the phenomenon under analysis, the effect on earnings is not altered (Groot and Maasen van den Brink 2000). So, independently of the method used, a number of studies that estimated the effects of over-education on earnings for developed and developing countries found that, overeducated workers tend to earn higher returns to their years of schooling than co-workers who are not over-educated, but lower returns

¹ Duncan and Hoffman (1981), Verdugo and Verdugo (1989), Sicherman (1991), Tsang et al. (1991), McGoldrick and Robst (1996) studied the phenomenon for the United States; Alpin et al. (1998), Green et al. (2002), Dolton and Vignoles (2000) and Chevalier (2003) for the UK; Hartog and Oosterbeek (1998) and Groot and Massen van den Brink (2000) for Holland; Bauer (2002) and Buchel and van Ham (2003) for Germany; Kiker et al. (1997) and Mendes de Oliveira et al. (2000) for Portugal; Alba-Ramirez (1993) for Spain. For an extensive review of overeducation in developed countries see McGuinness (2006) and for a recent survey on overeducation see Leuven and Oosterbeek (2011).

² Quinn and Rubb (2006) study the phenomenon for Mexico, Abbas (2008) for Pakistan and Mehta et al. (2011) for India, Mexico, the Philippines and Thailand, Mora (2005), Castillo (2007) and Herrera-Idárraga et al. (2012) for Colombia.

than workers with similar education who work in jobs that require the level of education that they possess.

In a previous study, Herrera-Idárraga et al. (2012), using micro-data for Colombia, find that after controlling for other characteristics and correcting for endogeneity, informal salary workers are more likely to be over-educated than formal workers. Thus it is possible that the formal-informal wage gap is driven, at least in part, by a less satisfactory matching of education-occupation in the informal sector and by the penalization in terms of wages that is derived from this mismatch. Actually the aim of this paper is to reexamine the wage gap between formal and informal workers taking into consideration that education-occupation mismatch is present in both sectors, using the case study of Colombia.

Colombian labor market constitutes a good case of study for several reasons. First, informality today is at center of economic and political debates in the country because the high levels that prevail. Second, in Colombia there is a high incidence of the minimum wage, i.e., a relatively high proportion of formal sector employees, 34.6%, receive a salary similar to the minimum (Arango et al. 2008) which points toward to the existence of important labor market rigidities. Third, previous studies have found over-education to exist in Colombia (Mora 2005, Castillo 2007, Dominguez-Moreno 2009 and Herrera-Idárraga et al. 2012).

This study contributes to the literature on informality and education-occupation mismatch by gauging if the return to years of required education, years of surplus education and years of deficit education differ across formal and informal sectors. If they do differ and if salaried informal workers are more penalized in terms of wages than their formal counterparts, then we can infer that part of the formal-informal wage gap might be originated in such a difference. The idea of distinguishing the difference in the returns from correct, over and under education for the two sectors is a novel contribution, as there is no previous contribution that considered this

difference before in all studies of which we know about informality³.

The empirical analysis consists of examining the returns to education taking into consideration the existence of educational mismatches in the formal and informal sector. For this purpose we first estimate the standard Duncan and Hoffman's specification (so called ORU wage equation) at the mean, using ordinary least square (OLS), and controlling for a rich set of observable individual and firm characteristics. Then, we examine if the returns to education for each of the education-occupation mismatch are not uniform along the wage distribution by using quantile regression estimation. In both cases the endogeneity sector choice is addressed.

Results for Colombia show that: i) consistent with previous literature, the return to an overeducated year is lower than the return to a required year of education, both in the formal and informal sector, ii) formal workers that possess the education required to do their job have a higher return to their education, around double, compared with their informal counterparts, iii) moreover, they have a higher return than informal workers who are overeducated, iv) the return to an overeducated year of education is higher in the formal sector than in the informal sector and v) the wage penalty of deficit schooling is almost the same across the two sectors. Moreover using quantile regression estimations we show that i) these returns vary along the wage distribution and ii) the pattern of variation along the distribution is not the same for formal and informal workers. More specifically, the returns to required education increases along the wage distribution for both type of workers, but the increase is more noticeable for formal workers. While returns to surplus education increases along the wage distribution for formal workers they almost remain constant for informal workers. We therefore conclude that adding measures of educational mismatch gives important information to the analysis of the formal/informal wage gap. In particular, we show that in the informal sector not only the returns

³ See, e.g., Magnac (1991), Nuñez (2002), Maloney and Nuñez (2004), Floréz (2002), Kugler and Kugler (2009) and Mondragón-Vélez et al. (2010) for Colombia; Gindling (1991) for Costa Rica; Pradhan and van Soest (1995) for Bolivia; Amuedo-Dorantes (2004) for Chile; Pratap and Quintin (2006) for Argentina; Tansel (2000) for Turkey; Marcouiller et al. (1997) and Gong and Van Soest (2002) for Mexico; Botelho and Ponczek (2011) for Brazil; Badaoui et al. (2008) for South Africa.

to education are lower, but the penalty that informal workers face due to educational mismatches in terms of wages are considerable higher than the one for their formal counterparts.

The rest of the paper is organized as follows. The next section gives a description of the data and some selected descriptive, while the empirical approach is presented in section 3. Section 4 summarizes the results regarding the estimates of the empirical models, and, finally, section 5 concludes.

2. Dataset and descriptive analysis

We use data from the Colombian Household Survey (CHS), a repeated cross-section conducted by the National Statistics Department (DANE), for 2010. The survey gathers information about employment conditions for population aged 12 or more including income, occupation and industry sector at two digit level, in addition to the general population characteristics such as sex, age, marital status and educational attainment and covers the thirteen mayor metropolitan areas in Colombia.

A sample of 34626 working individuals was drawn from the 2010 CHS. The analysis was restricted to salary workers that were not carrying formal studies aged between 15 and 60 years and who report working more than 16 hours per week. We do not include self-employed and employers workers in the analysis because their source of income is a combination of labor and physical capital and therefore may not be compared with earnings of other employees. Apart from this, self-employed workers' earnings would be expected to have a greater measurement error. Also, while comparing self-employed informal workers to their formal counterparts may be of interest, it has been shown in previous studies that self-employed in the informal sector corresponds more with a voluntary entry, while informal salaried work may correspond more closely to the standard queuing view, especially for younger workers (Perry et al. 2007; Bosh and Maloney, 2010). Excluding self-employed resulted in dropping 16941 individuals. We also exclude public employees from the sample since by nature they belong to the formal sector and

their wages might reflect institutional arrangements. After excluding observations with missing values or inconsistencies for the selected regressors, over 13797 individuals remained in our sample.

We classify workers as formal or informal according to whether they are covered by the social security system or not, in line with the definition proposed by the Seventeenth International Conferences of Labour Statisticians (ICLS).⁴ Thus, we define workers as formal if they contribute both to health and old-age insurance. For the purpose of measuring the incidence of the education-occupation mismatch we define required education using the statistical method in its mean and mode version. Under the statistical method required education is defined as the mean or mode level of schooling for each occupation. Individuals are classified as over-educated (under-educated) for a particular occupation if their level of education is higher (lower) than the required education. In the mean measure a worker is over-educated or under-educated if their completed level of schooling deviates by one standard deviation from the mean in their occupation.⁵ Regarding earnings, we have combined information from gross monthly income and worked hours in order to obtain gross hourly wages.

Table 1 contains mean hourly wages by job type and educational mismatch. As it can be seen informal workers are likely to earn less than formal workers, formal workers earn 78% more than what informal workers earn for the total sample. This large wage differential found here is in line with the findings of several other studies for other countries, and so far has been the centerpiece of the empirical analysis in the past. If formal and informal workers are classified by educational mismatch the wage gap is not the same across the different categories. For instance, overeducated formal workers earn 90% more than informal overeducated workers,

⁴ The definition of the Seventeenth International Conferences of Labour Statisticians (ICLS) of informal employment is "based on the characteristics of the individual's employment, job or position. A worker has an informal job if the employment relationship is, in law or in practice, not subject to national labour or social legislation. This condition of informal employment is observed in persons employed in both formal and informal enterprises, as well as in those employed in domestic service by households". (ILO's 2011 Labour Overview).

⁵ For purpose of brevity we only included the results obtained with the mean, as with the mode the results are not significantly different. The full set of results is available on request.

while undereducated formal workers earn 40% more than their informal peers. The formal – informal wage gap is also higher for the overeducated than for workers correctly matched in terms of education.

Table 1 also presents the formal-informal wage gap at different quantiles. As it can be seen the wage gap is not homogeneous along the wage distribution and across the different education-occupation mismatches. The first thing to be noticed is that the hourly wage at the lower quantile for correct and overeducated formal workers are both equal to the minimum wage⁶, while an undereducated formal worker perceives a wage slightly lower. This finding conforms to the notion that the minimum wage is binding in the formal sector, especially for correct and overeducated workers that represent 93% of formal workers. The formal-informal wage gap among the least skilled, measured by the lower quantile of the wage distribution, is considerably lower for overeducated workers compare to correct and undereducated workers. This could be indicating that a formal worker in the lower part of the distribution and regardless of his education will be rewarded with a wage similar to the minimum wage, while informal wages are determined freely. This possibility to set wages freely allows informal sector to pay a considerably lower wage to correct and undereducated workers, while somehow rewarding overeducated workers. In contrast, at the middle and, particularly, at the upper part of the distribution the formal-informal wage gap is substantially higher for overeducated workers compare to correct and undereducated workers. Thus, this simple preliminary evidence, at the mean and at different quantiles, indicates that educational mismatch may be a key aspect in order to get a better understanding of the formal – informal wage gap.

Table 2 presents some basic summary statistics concerning the distribution of the observed workers' and firms' characteristics that may be driving the earnings differentials. It shows information for the entire sample of workers, and distinguishing between those working in the formal and in the informal sectors. From the raw data it is deduced that formal workers seems more likely to be overeducated than informal workers, while informal workers seems more

⁶ The minimum wage in Colombia in 2010 was 515,000 pesos, equivalent to 2503.47 pesos per hour.

likely to be undereducated than their formal counterparts. Furthermore the incidence of correctly educated workers is similar in the two sectors. However, these differentials in the incidence of over- and under-education may just be caused by a composition effect, i.e. formal workers are more educated whereas informal worker are less educated⁷. In fact, formal workers in our sample are more likely to have higher education or more (44%), whereas informal workers are more likely to have basic secondary and secondary (22% and 36% respectively). There is not significant difference in age and experience between workers in both groups. In contrast, there are some notable differences in the average tenure between sectors; formal workers tend to accumulate much more tenure than informal workers, suggesting higher stability of employment for formal workers. As a matter of fact, 95% of formal workers had signed a contract, and 65% of them of a permanent type, in contrast with only 18% of informal workers who have a contract, and only 10% having a permanent one. On the other hand, as can be seen, the percentage of female workers in the formal sector is higher than in the informal. This may be due to the fact that our sample excludes self-employed individuals and unpaid family workers. A much larger proportion of the workforce in the formal sector is married. In terms of the occupational structure, informal workers are more likely to be found in unskilled manufacturing and agricultural occupations (43%). Those in the formal sector are also more likely to be found in unskilled manufacturing and agricultural occupations like informal workers but at a lower rate (25%), followed by administrative staff (24%). There is little difference in the average hours of work in the two sectors. Firms with less than 3 regular employees are substantially more likely to be part of the informal sector. In contrast, larger firms employ much of the formal-sector labor force with a workforce greater than one hundred.

3. Wage estimates - Empirical Strategy

⁷ Herrera et al. (2012) show that a sorting effect drives the gap in the raw propensities, and that when comparing formal and informal workers with similar individual and firm characteristics, those in the former group have a lower propensity to be overeducated.

An important number of former studies that intended to measure the formal – informal sector wage gap have simply estimated a Mincerian wage equation using OLS. The framework for the empirical analysis is a model in which the wage of an individual i in sector j is given by:

$$W_{ij} = \alpha_j S_{ij} + \beta_j X_{ij} + \varepsilon_{ij} \quad (1)$$

where W_{ij} denotes the log of the hourly wage of the individual i in the sector j , formal (F) or informal (I), S_{ij} the years of acquire education, X_{ij} denotes the set of other characteristics (e.g. experience, tenure, gender) that affect the wage of this individual; and α_j and β_j is a vector of prices or returns associated with years of acquire education and other characteristics that affect wages.

The typical specification adopted to estimate the effect on earnings of education – occupation mismatch is based also on the Mincerian wage equation. However, the general educational mismatch specification varies slightly in that the variable of acquired years of schooling is decomposed into three variables: required, surplus and deficit education, following Duncan and Hoffman (1981) formulation. Over-education is the amount of years of schooling a worker has acquired in excess of the required education needed to perform his job. Under-education entails the opposite. Under this framework wages are a function of over, required and deficit years of education (so-called ORU wage equation). That is:

$$W_{ij} = \alpha_{ij} S_{ij}^r + \alpha_{oj} S_{ij}^o + \alpha_{uj} S_{ij}^u + \beta_j X_{ij} + v_{ij} \quad (2)$$

where S^r is years of required education, S^o is years of surplus education above the required level and S^u is years of deficit schooling below the required level. Then, under this wage equation the returns from additional education are α_{oj} for surplus years, α_{rj} for required years, and α_{uj} for deficit years of education. Notice that instead of imposing the same return in the two sectors, we

allow them to differ for workers in each sector j , formal or informal.

Next we want to analyze the returns to education and the effects of occupation-education mismatch on the entire wage distribution for formal and informal workers, by using linear quantile regression estimates. By estimating linear quantile regressions we are able to examine the heterogeneous effect of education at different points in the wage distribution. Moreover, quantile regression estimates are robust to the outliers of the dependent variable and they are also more efficient than the OLS under non-normality of the error terms. For any worker i in sector j we can write the τ^{th} quantile of the hourly wage distribution conditional on actual years of education (S_{ij}) and other characteristics (X_{ij}) as:

$$F_{W_{ij}}^{-1}(\tau | S_{ij}, X_{ij}) = S_{ij}\alpha_j(\tau) + X_{ij}\beta_j(\tau), \quad \forall \tau \in [0,1] \quad (3)$$

where $F_{W_{ij}}^{-1}(\tau | S_{ij}, X_{ij})$ is the τ^{th} quantile of W_{ij} conditional to S_{ij} and X_{ij} . The estimated quantile regression (QR) coefficients can be interpreted as the rates of return to actual education and other characteristics at different points of the conditional wage distribution. Similarly for any worker i in sector j we can write the τ^{th} quantile of the hourly wage distribution conditional to years of required education (S_{ij}^r), years of surplus education (S_{ij}^o), years of deficit education (S_{ij}^u), and other characteristics (X_{ij}) as:

$$F_{W_{ij}}^{-1}(\tau | S_{ij}^r, S_{ij}^o, S_{ij}^u, X_{ij}) = S_{ij}^r\alpha_j^r(\tau) + S_{ij}^o\alpha_j^o(\tau) + S_{ij}^u\alpha_j^u(\tau) + X_{ij}\beta_j(\tau), \quad \forall \tau \in [0,1] \quad (4)$$

The specifications formulated so far (eqs. 1 to 4) neglect the existence of non-observable characteristics that could simultaneously affect wages and the sector in which the individuals are currently working. This will cause to obtain not only biased, but also inconsistent coefficients of the return to education. To account for this concern, we implement the conventional approach of including a selection correction in the wage regressions for each sector. This entails a two-stage estimation process. In a first stage a reduced-form probit model of the formal vs. informal decision is estimated and a sample selection correction term is

obtained. In stage two, the correction term is incorporated into conventional Mincerian semi-log earnings functions for the formally employed and informally employed (see, e.g., Gong and van Soest 2002; Günther and Launov; 2012).

The selection process of the sector of employment follows the latent model:

$$E_i^* = \gamma Z_i + \mu_i \quad (5)$$

where E_i^* is a latent variable that determines the sector j (= formal, informal) in which individual i is employed, Z_i is a vector of observed individual characteristics included in X_i in the wages equations plus some other variable(s) for be employed in the formal or informal sector, and μ_i is the error term.

The observed binary variable E_i is related to the latent variable E_i^* as follows:

$E_i = 1$ if the individual is in the formal sector ($E_i^* \geq 0$)

$E_i = 0$ otherwise

Estimates of returns based on the wage equations (1) to (4), leaving aside the selection equation (5), are biased and inconsistent if the error term of the selection equation and the error terms of the wage equations are correlated, e.g. $cov[\mu_i, \varepsilon_{ij}] = \rho_j \neq 0$.

In the case of estimates at the mean, consistent estimates can be obtained by maximum likelihood considering the information from the selection and wage equations or, alternatively, by applying the two-step method proposed by Heckman (1979). The so-called Heckit method includes the inverse Mills ratio in the wage equation as an additional regressor to obtain wages conditional on being in the formal or informal sector.

While the methods for correcting sample selection for mean regression are well acknowledged, there are few known approaches to correct for selectivity bias in quantile regression models and there is little consensus regarding the most appropriate correction procedure. Buchinsky (1998) suggests an approach to approximate the selection term by a power series expansion of the inverse of the Mill's ratio and is the most common approach used so far for correcting selectivity in quantile regression models (Garcia et al., 2001; de la Rica et al, 2008; Albrecht et al, 2009).

4. Returns to education across sectors – empirical results

4.1 OLS regressions

Table 3 presents the coefficients obtained from estimating the Mincer wage equation (1) and the coefficients of estimating the ORU wage equation (2). Estimates were done separately for formal and informal workers. A simple specification for the two wage equations was used to account fully the effect of human capital variables. It includes as explanatory variables the number of years of education (actual years of education in the Mincerian wage equation and years of education decomposed into surplus, required and deficit in the ORU wage equation), the years of experience and its square, the months of tenure with the current firm and its square, and the gender of the individual. The results of this simple specification are presented in the first column of each estimated wage equation.

However as it has been shown in the descriptive analysis, formal and informal workers differ significantly in firm characteristics and individual characteristics, beside those related to human capital. For instance given that firms tend to be larger in the formal sector and larger firm pay more, formal workers could obtain a higher return to their education just because they are more prone to work in large firms while informal workers are more likely to work in small firms. Thus to ensure that the comparison of the returns to education across the two sectors is done for

observably similar workers, a more comprehensive specification that includes additional controls was used for the two wage equations. Besides, including additional individual and job characteristics also allow us to disentangle to what extent these observable characteristics explain the average wage differentials across formal/informal workers. Those controls include dummy variables for marital status, head of household, occupation, contract signed, size of the firm, industry sector, hours worked and a dummy variable indicating the metropolitan area. The results of this more comprehensive specification are shown in the second column of each estimated wage equation.

We start by describing the results of the Mincerian wage equation for the simple specification (columns labeled 1). The results show that education is better rewarded in the formal sector than in the informal sector, since each additional year of schooling increase hourly wages by 10.08% for formal workers, and this is around double that for the informal workers, 5.43%. Once additional controls are accounted for (columns 2) the return to schooling estimated for both sectors is lower, especially for formal workers. Each additional year of schooling increased hourly wage by 6.75% for formal workers and by 3.78% for informal workers. Nevertheless, the finding that formal workers have a higher return to their education than informal workers still holds.

Considering the existence of educational mismatches gives an interesting picture of the difference in the returns to schooling across the two sectors. Table 3 also presents the returns associated with schooling when educational mismatches are present –the ORU wage equation (2). Consistent with previous literature i) the returns to surplus schooling are lower than the returns to required schooling, ii) a year of deficit schooling carries a wage penalty for both sectors, and iii) the returns on required education are higher than that on actual or attained education in the Mincer equation. As it can be seen, the returns to required and to surplus schooling are higher in the formal sector than in the informal. One additional year of required education raises hourly wages by 13.23% in the formal sector and by 7.63% in the informal.

Years of surplus education are associated with an earning increase of 9.31% for formal workers and 4.16% for informal workers. Noteworthy is that the penalty of deficit schooling is almost the same across sectors, around 3%-4%. As with the results from estimating the Mincerian wage equation, when additional controls are introduced in the estimation of the ORU wage equation the returns to schooling are lower, mainly for formal workers, but remain significantly higher than those for informal workers. To sum up, formal workers have higher returns to their years of education than informal workers, and this is so in the presence of educational mismatch. Moreover overeducated informal workers are double penalized, they obtain a lower return to their education for the fact of being in the informal sector and they face a second penalty associated with the lower returns they obtain because of the inappropriate use of their education for performing their job.

4.2 Quantile regressions

The OLS results provide the return estimates at the mean of the wage distribution, which may cover important differences in the return estimates at different points of the wage distribution. Table 4 presents the quantile regressions results obtained from estimating the Mincerian wage equation - eq. (3) - in the upper panel and the ORU wage equation - eq. (4) – in the lower panel. Both equations were estimated using all set of controls (dummy variables for marital status, head of household, occupation, contract signed, size of the firm, sector industry, hours worked and metropolitan area). The results reveal that schooling is not uniformly rewarded in the labor market along the wage distribution. More specifically, the return to actual education increases along the wage distribution for formal workers, while a comparable pattern is not observable for informal workers. Interestingly, the difference in the return to actual education for formal and informal workers in the 25th quantile is minimal, while at the 75th quantile the return to actual education for formal workers is around double than that for informal workers. That the returns to education for formal workers in the 25th quantile are very similar to those of informal workers counterparts can be the result of the existence of a minimum wage, binding only for the formal

sector, which could be imposing an important distortion to the returns to education to formal sector workers at this part of the distribution.

The results obtained for the ORU specification in eq. 4 show that, the returns to surplus and required education behaves similarly to the returns to actual education, increases along the wage distribution for formal workers and remains almost constant for informal workers across the different quantiles. And the penalty associated to deficit education has a non-monotonic behavior for formal and informal workers. These patterns are summarized in Figure 1, which plot the estimated returns at different percentiles for formal and informal workers. As it can be seen the returns to education is not homogenous along the wage distribution and this heterogeneous behavior is very different for formal and informal workers.

A more detail inspection of the lower panel of Table 4 reveals key information. For instance, differences in the educational returns between formal and informal workers with the same educational-occupational mismatching are present at the 25th quantile, although less sizeable than the differences presented in the 75th quantile. Formal workers that possess the education required to do their job have a higher return to their education, slightly higher in the lowest quantile and around double in the upper. An overeducated formal worker in the lower part of the distribution obtain a return of his years of surplus education similar to the return obtain by an informal worker for the years of education required to perform his job, 3.48% and 4.86% respectively. Meanwhile the returns to surplus education for formal workers at 75th quantile of the distribution are larger than the returns to required education for informal workers, 8.64% and 6.66% correspondingly. Interestingly, the pay penalty associated with deficit years of education is considerable lower for formal workers compare to the one faced by informal workers, at the lower and upper part of the distribution.

The results from the quantile regression leads to the conclusion that formal workers are able to obtain a higher reward for their education even in the presence of educational mismatch, and this is so along all the wage distribution. Furthermore, the returns to surplus education increases

considerably for formal workers along the wage distribution suggesting that this type of jobs represents better employment opportunities for overeducated workers. This probably reflect the fact that formal workers may take advantage of the higher productivity⁸ that is present in formal jobs, which may boost the returns to education. Meanwhile, informal workers receive a lower remuneration to their education compared to the one obtained by their formal peers. This difference in returns to education between formal and informal workers is even more accentuated in the upper part of the distribution. More importantly, informal overeducated workers do not face higher returns once they move up the wage distribution, implying that informal jobs may constraint the use of education and its returns.

4.3 Sample selection

Our estimates of the wage equations, when taking into account that unobservable variables might influence both wages and the choice of formal/informal employment, are summarized in Table 5 for the estimates at the mean. These results correspond to estimates of the wages equations augmented by a selection correction term for each sector, using the presence of children in the household and the average number of years of schooling of other household members as an instrument for assignment into the formal or informal sector. The reason for choosing this selection variables is motivated by the fact that these variables should contain household-specific characteristics that influence an individual's choice regarding formal or informal employment, but at the same time have no direct impact on the earning potentials of individuals (Günther and Launov, 2012 use similar variables as exclusions restrictions). As it can be seen, once the selectivity is corrected the returns to schooling remains higher for formal workers in the two wage equations estimated (Mincer and ORU). It is important to note that the selection term (*Mills lambda*) is positive and statistically significant for formal workers. This

⁸ The productivity of formal firms could be higher than that of informal firms because a higher capital-labor ratio, caused by the fact that informal firms may have less access to credit (Amaral and Quintin, 2006). Another reason is that informal firms continue to operate at a small size that allows them to scape from government control and, therefore, cannot exploit possible economies of scale.

result can be interpreted as follows: a worker that has a higher probability of working in the informal sector, due to his observable characteristics, could end up working in the formal sector thanks to unobservable factors (e.g. job-search networks or ability) and gets a higher return to his education (Tannuri-Pianto et al., 2004 find a similar result for Bolivia). In the case of informal workers the selection term is insignificantly different from zero. This implies that there is no correlation between the error terms of the selection equation in (5) and that of the wage equation for informal workers, and thus that the estimates given in Table 2 for informal workers are indeed unbiased.

We also re-estimate the quantile regressions of eq. (3) and eq. (4) introducing the inverse of the Mills's ratio and its square, following the Buchinsky (1998) procedure for correcting for selection bias. The results are presented in Table 6. It can be observed that the pattern of estimated returns and differences between formal and informal workers reported and discussed in the previous section do not vary significantly when selection is accounted for.

All in all, from these results we can assert that the major conclusion on the higher penalty associated to educational mismatch for informal workers remains when controlling for the correlation between the error terms in the selection and the wage equations.

7. Conclusions

There is now substantial body of literature addressing the wage differential between formal and informal workers for developing countries, theoretically and empirically. In empirical analysis wage equations are estimated for each group of workers, where one of the key factors is education (and its returns). There are papers that have gone beyond the difference in the mean, finding that the wage gap is not stable along the wage distribution, estimating quantile regressions. Some works have questioned the existence of a wage gap (i.e. market segmentation) given the endogeneity caused by unobservable characteristics of the individuals, such as skills. As far as we know there is no study that considered the fact that education-occupation mismatching is present in both formal and informal sector, and that this may be

driving, at least in part, the formal/informal wage gap. In this paper we have reexamined the wage gap between formal and informal workers taking into consideration that education-occupation mismatch is present in both sectors, using the case study of Colombia.

Results for Colombia show that formal workers have a higher return to their education, around double, compared with their informal counterparts. These returns vary along the wage distribution and we have shown that the pattern of variation along the distribution is not the same for formal and informal workers. Adding measures of educational mismatch gives important information to the analysis of the formal–informal wage gap. In particular, we showed that in the informal sector not only the returns to education are lower, but the penalty that informal workers face due to educational mismatches in terms of wages are considerable higher than the one faced by their formal counterparts. Therefore, there is a second penalty associated with educational mismatches that puts informal workers at a greater disadvantage compare to formal workers.

If labor market segmentation is what is driving the existence of overeducation in a developing country, as Herrera et al. 2012 claim that it may be the case, then policies engaged with reducing informality could also have other positive effects apart from those commonly known, better quality jobs. Reducing informality may reduce the situation where a highly schooled worker takes a job with low-skill requirements and consequent a low pay. This evidence should be taken into consideration when assessing the issue of informality in the labor market of developing countries since it is likely to affect the allocation of skilled and unskilled workers in formal and informal jobs, and the incentives to accumulate education.
